PREFACE

TO FIRST EDITION, 1872.

SHOULD experts in engineering complain that they do not find anything of interest in this volume, the writer would merely remind them that it was not his intention that they should. The book has been prepared for *young* members of the profession; and one of the leading objects has been to elucidate, in plain English, a few important elementary principles which the savants have enveloped in such a haze of mystery as to render pursuit hopeless to any but a confirmed mathematician.

Comparatively few engineers are good mathematicians; and in the writer's opinion, it is fortunate that such is the case; for nature rarely combines high mathematical talent, with that practical tact, and observation of outward things, so essential to a successful engineer.

There have been, it is true, brilliant exceptions; but they are very rare. But few even of those who have been tolerable mathematicians when young, can, as they advance in years, and become engaged in business, spare the time necessary for retaining such accomplishments.

Nearly all the scientific principles which constitute the foundation of civil engineering are susceptible of complete and satisfactory explanation to any person who *really* possesses only so much elementary knowledge of arithmetic and natural philosophy as is *supposed* to be taught to boys of twelve or fourteen in our public schools.*

* Let two little boys weigh each other on a platform scale. Then when they balance each other on their board see-saw, let them see (and measure for themselves) that the lighter one is farther from the fence-rail on which their board is placed, in the same proportion as the heavier boy outweighs the lighter one. They will then have learned the grand principle of the *lever*. Then let them measure and see that the light one see-saws farther than the heavy one, in the same proportion; and they will have acquired the principle of *virtual velocities*. Explain to them that *equality of moments* means nothing more than that when

The little that is beyond this, might safely be intrusted to the savants. Let them work out the results, and give them to the engineer *in intelligible language.* We could afford to take their words for it, because such things are their specialty; and because we know that they are the best qualified to investigate them. On the same principle we intrust our lives to our physician, or to the captain of the vessel at sea. Medicine and seamanship are their respective specialties.

If there is any point in which the writer may hope to meet the approbation of proficients, it is in the accuracy of the tables. The pains taken in this respect have been very great. Most of the tables have been entirely recalculated expressly for this book; and one of the results has been the detection of a great many errors in those in common use. He trusts that none will be found exceeding one, or sometimes two, in the last figure of any table in which great accuracy is required. There are many errors to that amount,

---

they seat themselves at their measured distances on their see-saw, *they balance each other.* Let them see that the weight of the heavy boy, when multiplied by his distance in feet from the fence-rail amounts to just as much as the weight of the light one when multiplied by his distance. Explain to them that each of the amounts is in *foot-pounds.* Tell them that the lightest one, because he see-saws so much faster than the other, will bump against the ground just as hard as the heavy one; and that this means that *their momentums are equal.* The boys may then go in to dinner, and probably puzzle their big lout of a brother who has just passed through college with high honors. They will not forget what they have learned, for they learned it *as play,* without any ear-pulling, spanking, or keeping in. Let their bats and balls, their marbles, their swings, &c, once become their philosophical apparatus, and children may be taught (*really* taught) many of the most important principles of engineering before they can read or write. It is the ignorance of these principles, so easily taught even to children, that constitutes what is popularly called "THE PRACTICAL ENGINEER;" which, in the great majority of cases, means simply an ignoramus, who blunders along without knowing any other reason for what he does, than that he has seen it done so before. And it is this same ignorance that causes employers to prefer this practical man to one who is conversant with principles. They, themselves, were spanked, kept in, &c, when boys, because they could not master leverage, equality of moments, and virtual velocities, enveloped in x's, p's, Greek letters, square-roots, cube-roots, &c, and they naturally set down any man as a fool who could. They turn up their noses at science, not dreaming that the word means simply, *knowing why.* And it must be confessed that they are not altogether without reason; for the savants appear to prepare their books with the express object of preventing purchasers, (they have but few *readers,*) from learning why.

especially where the recalculation was very tedious, and where, consequently, interpolation was resorted to. They are too small to be of practical importance. He knows, however, the almost impossibility of avoiding larger errors *entirely;* and will be glad to be informed of any that may be detected, except the final ones alluded to, that they may be corrected in case another edition should be called for. Tables which are absolutely reliable, possess an intrinsic value that is not to be measured by money alone. With this consideration the volume has been made a trifle larger than would otherwise have been necessary, in order to admit the stereotyped sines and tangents from his book on railroad curves. These have been so thoroughly compared with standards prepared independently of each other, that the writer believes them to be absolutely correct.

In order to reduce the volume to pocket-size, smaller type has been used than would otherwise have been desirable.

Many abbreviations of common words in frequent use have been introduced, such as abut, cen, diag, hor, vert, pres, &c, instead of abutment, center, diagonal, horizontal, vertical, pressure, &c. They can in no case lead to doubt; while they appreciably reduce the thickness of the volume.

Where prices have been added, they are placed in footnotes. They are intended merely to give an approximate or comparative idea of value; for constant fluctuations prevent anything farther.

The addresses of a few manufacturing establishments have also been inserted in notes, in the belief that they might at times be found convenient. They have been given without the knowledge of the proprietors.

The writer is frequently asked to name good elementary books on civil engineering; but regrets to say that there are very few such in our language. "Civil Engineering," by Prof. Mahan of West Point; "Roads and Railroads," by the late Prof. Gillespie; and the "Handbook of Railroad Construction," by Mr. George L. Vose, Civ. Eng. of Boston, are the best. The writer has reason to know that a new edition of the last, now in press, will be far

superior to all predecessors; and better adapted to the wants of the young engineer than any book that has appeared.

Many of Weale's series are excellent. Some few of them are behind the times; but it is to be hoped that this may be rectified in future editions. Among pocket-books, Haswell, Hamilton's Useful Information, Henck, Molesworth, Nystrom, Weale, &c, abound in valuable matter.

The writer does not include Rankine, Moseley, and Weisbach, because, although their books are the productions of master-minds, and exhibit a profundity of knowledge beyond the reach of ordinary men, yet their language also is so profound that very few engineers can read them. The writer himself, having long since forgotten the little higher mathematics he once knew, cannot. To him they are but little more than striking instances of how completely the most simple facts may be buried out of sight under heaps of mathematical rubbish.

There is no table of errata, because no errors are known to exist except two or three of a single letter in spelling; and which will probably escape notice.

JOHN C. TRAUTWINE.

PHILADELPHIA, *November* 13th, 1871.

FROM PREFACE

OF TWENTIETH EDITION, 1918.

As in our preceding editions, all new work and all revisions have been the subject of our personal attention, and "scissors-and-paste" methods have been scrupulously avoided.

As in all cases heretofore, every rule and every formula and every description of methods, etc., can be readily understood by anyone, engineer or layman, understanding the use of common and decimal fractions, of roots and powers, of logarithms, and of elementary plane trigonometry. On the other hand, one who is not possest of this very meagre stock of mathematical knowledge will hardly approach engineering problems, even as an amateur . . .

. . . Extraordinary precautions have been taken for the protection of our readers against the occurrence of typographical and other errors. In this, as in previous editions, special attention has been given to the matter of typography, which, like other steps in manufacture, has been under our own direct personal control. This includes the preparation of illustrations . . .

The manuscript was thoroly checkt before it was sent to the printer. The first proof was minutely read by ourselves, as well as by the printer. In this work we used a new apparatus, of our own invention, to facilitate the verification of punctuation, of bold and italic characters, etc. Another device of our own was used in comparing successive proofs, to detect any accidental shifting of type matter.. . .

JOHN C. TRAUTWINE JR.
JOHN C. TRAUTWINE 3D.

Philadelphia, *August, 1918.*

Pages xii to xix inclusive are here omitted and reserved, in order to provide space for future additions to Prefaces or to the Table of Contents.

MATHEMATICS.

MATHEMATICAL SYMBOLS.

$+$ **Plus, positive, add.** 1.414 + means 1.414 + other decimals.
$-$ Minus, negative, subtract.
$\pm$ Plus or minus, positive or negative. Thus, $\sqrt{a^2} = \pm a$.
$\mp$ Minus or plus.
$\times$ Multiplied by, times. Thus, $x \times y = x.y = x\,y$; $3 \times 4 = 12$.
$\div$: / Divided by. Thus, $a \div b = a : b = a/b = \frac{a}{b}$
: : Proportion. Thus, $a : b :: c : d$, as a is to b, so is c to d.
$=$ Equals, is equal to
$>$ Is greater than. Thus, $6 > 5$.
$<$ Is less than. Thus, $5 < 6$.
$\neq$ Is not equal to
$\gtrless$ Is greater or less than.
$\ngtr$ Is not greater than.
$\nless$ Is not less than.
$\geqq$ Is equal to or greater than.
$\leqq$ Is equal to or less than.
$\propto$ Is proportional to, varies with.
∞ Infinity.
$\perp$ Is perpendicular to.
$\angle$ $\measuredangle$ Angle.
$\sim$ Is similar to.
$\parallel$ Is parallel to.
$\sqrt{}$ $\sqrt{}$ Root of. Thus, $\sqrt[2]{a}$ or $\sqrt{a}$ = square root of a, $\sqrt[3]{a}$ = 3d or cube root of a. $\sqrt[n]{a}$ = nth root of a.
( ) Parenthesis. [ ] Brackets. { } Braces. —— Vinculum. Quantities enclosed or covered by the symbol are to be taken together.
$\because$ Since, because.
$\therefore$ Hence, therefore.
° Degrees.
′ Minutes of arc,* feet.
″ Seconds of arc,* inches.
′ ″ ‴ etc. Prime, second, third, etc. Distinguishing accents. Thus, a' a prime; a'', a second, etc.
$\pi = \frac{\text{Circumference}}{\text{Diameter}} = 3.14159265+$, arc of semicircle, or 180°.
E, Modulus of elasticity.
e ϵ, Base of Napierian, natural or hyperbolic logarithms = 2.718281828.
g, Acceleration of gravity = approximately 32.2 feet per second per second = approximately 9.81 meters per second per second.

---

*Minutes and seconds of time, formerly also denoted by ′ and ″, are now denoted by m and s, or by min and sec, respectively.

THE GREEK ALPHABET.

This alphabet is inserted for the benefit of those who have occasion to consult scientific works in which Greek letters are used, and who find it inconvenient to memorize the letters

Greek letters. Capital	Small	Name.	Approximate equivalent.	Commonly used to designate
Α	α	Alpha	a	Angles, Coefficients.
Β	β	Beta	b	" "
Γ	γ	Gamma	g	" " Specific gravity.
Δ	δ	Delta	d	" " Density, Variation.
Ε	ε	Epsilon	e (short)	Base of hyperbolic logarithms = 2.7182818. Eccentricity in conic sections.
Ζ	ζ	Zeta	z	Co-ordinates, Coefficients.
Η	η	Eta	e (long)	" "
Θ	θ ϑ	Theta	th	Angles.
Ι	ι	Iota	i	
Κ	κ	Kappa	k	
Λ	λ	Lambda	l	Angles, Coefficients, Latitude.
Μ	μ	Mu	m	" "
Ν	ν	Nu	n	"
Ξ	ξ	Xi	x	Co-ordinates.
Ο	ο	Omicron	o (short)	
Π	π	Pi	p	Circumference ÷ diameter.*
Ρ	ρ	Rho	r	Radius, Ratio.
Σ	σ ς	Sigma	s	Distance (space).†
Τ	τ	Tau	t	Temperature, Time.
Υ	υ	Upsilon	u or y	
Φ	φ	Phi	ph	Angles, Coefficients.
Χ	χ	Chi	ch	
Ψ	ψ	Psi	ps	Angles
Ω	ω	Omega	o (long)	Angular velocities.

* The small letter π (*pi*) is universally employed to designate the number of times ($= 3.14159265\ldots$) the diameter of a circle is contained in the circumference, or the radius in the semi circumference. In the circular measure of angles, an angle is designated by the number of times the radius of any circle is contained in an arc of the same circle subtending that angle. π then stands for an angle of 180° (= two right angles), because, in any circle, $\pi \times$ radius = the semi-circumference

The capital letter Π (*pi*) is used by some mathematical writers to indicate the product obtained by multiplying together the numbers 1, 2, 3, 4, 5 . . . etc., up to any given point. Thus, $\Pi 4 = 1 \times 2 \times 3 \times 4 = 24$.

† The capital letter Σ (*sigma*) is used to designate a *sum*. Thus, in a system of parallel forces, if we call each of the forces (irrespective of their amounts) F, then their resultant, which is equal to the (algebraic) sum of the forces, may be written $R = \Sigma F$.

ARITHMETIC.

FACTORS AND MULTIPLES.

(1) Factors of any number, n, are numbers whose product is $= n$. Thus, 17 and 4 are factors of 68, so also are 34 and 2; also 17, 2, and 2.

(2) A prime number, or **prime,** is a number which has no factors, except itself and 1; as 2, 3, 5, 19, 233.

(3) A common factor, common divisor or **common measure,** of two or more numbers, is a number which exactly divides each of them. Thus, 3 is a common divisor of 6, 12, and 18

(4) The highest common factor or **greatest common divisor,** of two or more numbers, is called their **H. C. F.** or their **G. C. D.** Thus, 6 is the H. C. F. of 6, 12, and 18.

(5) To find the H. C. F. of two or more numbers; find the prime factors of each, and multiply together those factors which are common to all, taking each factor only once. Thus, required the H. C. F. of 78, 126, and 234.

$$\begin{array}{ll} 78 & 2 \times 3 \times 13 \\ 126 & 2 \times 3 \times 3 \times 7 \\ 234 & 2 \times 3 \times 3 \times 13 \end{array}$$

and H. C. F. $= 2 \times 3 = 6$.

(6) To find the H. C. F. of two large numbers; divide the greater by the less; then the less by the remainder, A; A by the second remainder, B; B by the third remainder, C; and so on until there is no remainder. The last divisor is the H. C. F. Thus, required the H. C. F. of 575 and 782.

```
575)782(1
    575
  A 207)575(2
        414
      B 161)207(1
            161
          C 46)161(3
               138
             D 23)46(2      H. C. F. = D = 23.
                  46
                   0
```

(7) A common multiple of two or more numbers is a number which is exactly divisible by each of them.

(8) The least common multiple of two or more numbers is called their **L. C. M.**

(9) To find the L. C. M. of two or more numbers; find the prime factors of each. Multiply the factors together, taking each as many times as it is contained in that number in which it is oftenest repeated. Thus, required the L. C. M. of 7, 30, and 48.

$$\begin{aligned} 7 &= 7 \\ 30 &= 2 \times 3 \times 5 \\ 48 &= 2 \times 2 \times 2 \times 2 \times 3 \end{aligned}$$

$$\text{L. C. M.} = 7 \times 2 \times 2 \times 2 \times 2 \times 3 \times 5 = 1680.$$

(10) To find the L. C. M. of two large numbers; find the H. C. F., as above; and, by means of it, find the other factors. Then find the product of the factors, as before. Thus, required the L. C. M. of 575 and 782. As above,

H. C. F. $= 23$; $\frac{575}{23} = 25$; and $\frac{782}{23} = 34$. Hence,

$$\begin{aligned} 575 &= 23 \times 25 \\ 782 &= 23 \times 34 \end{aligned}$$

and L. C. M. $= 23 \times 25 \times 34 = 19{,}550$.

FRACTIONS.

(1) A common denominator of two or more fractions is a common multiple of their denominators.

(2) The least common denominator, or L. C. D., of two or more fractions is the L. C. M. of their denominators.

(3) To reduce to a common denominator. Let

N = the new numerator of any fraction
n = its old numerator
d = its old denominator
C = the common denominator

Then

$$N = n\frac{C}{d}$$

Thus, $\frac{3}{4}, \frac{5}{6}, \frac{7}{8}$. C = L. C. M. of denominators = 24.

$$\frac{3}{4} = \frac{3\times\frac{24}{4}}{4\times\frac{24}{4}} = \frac{3\times 6}{4\times 6} = \frac{18}{24};\ \frac{5}{6} = \frac{5\times 4}{6\times 4} = \frac{20}{24};\ \frac{7}{8} = \frac{7\times 3}{8\times 3} = \frac{21}{24}.$$

If none of the denominators have a common factor, then C=the product of all the denominators, $\frac{C}{d}$ = the product, P, of all the *other* denominators, and N = P n

Thus, $\frac{2}{3}, \frac{1}{4}, \frac{5}{7}$. C = 84

$$\frac{2}{3} = \frac{2\times 4\times 7}{84} = \frac{56}{84},\ \frac{1}{4} = \frac{1\times 3\times 7}{84} = \frac{21}{84};\ \frac{5}{7} = \frac{5\times 3\times 4}{84} = \frac{60}{84}.$$

(4) Addition and Subtraction. If necessary, reduce the fractions to a common denominator, the lower the better. Add or subtract the numerators. Thus,

$$\frac{1}{2}+\frac{1}{2} = \frac{2}{2} = 1;\ \frac{3}{4}+\frac{1}{4} = \frac{4}{4} = 1;\ \frac{3}{4}+\frac{5}{9} = \frac{27}{36}+\frac{20}{36} = \frac{47}{36} = 1\frac{11}{36};$$

$$\frac{3}{4}+\frac{7}{8} = \frac{6}{8}+\frac{7}{8} = \frac{13}{8} = 1\frac{5}{8}.$$

$$\frac{3}{4}-\frac{1}{4} = \frac{2}{4} = \frac{1}{2};\ \frac{3}{4}-\frac{5}{9} = \frac{27}{36}-\frac{20}{36} = \frac{7}{36};\ \frac{7}{8}-\frac{3}{4} = \frac{7}{8}-\frac{6}{8} = \frac{1}{8}.$$

(5) Multiplication. Multiply together the numerators, also the denominators, cancelling where possible. Thus.

$$\frac{1}{2}\times\frac{1}{2} = \frac{1}{4};\ \frac{3}{4}\times\frac{1}{4} = \frac{3}{16};\ \frac{3}{4}\times\frac{5}{9}\times\frac{2}{3} = \frac{5}{18};$$

$$3\frac{4}{7}\times 1\frac{2}{3} = \frac{25}{7}\times\frac{5}{3} = \frac{125}{21} = 5\frac{20}{21};\ \frac{2}{3}\times\frac{3}{5} = \frac{2}{5};$$

$$\frac{3}{4}\text{ of }\frac{1}{2}\text{ of }\frac{5}{3}\text{ of }\frac{7}{5} = \frac{3}{4}\times\frac{1}{2}\times\frac{5}{3}\times\frac{7}{5} = \frac{7}{8}.$$

(6) Division. Invert the divisor and multiply. Thus,

$$\frac{1}{2}\div\frac{1}{2} = \frac{1}{2}\times\frac{2}{1} = \frac{2}{2} = 1;\ \frac{3}{4}\div\frac{1}{4} = \frac{3}{4}\times\frac{4}{1} = \frac{3}{1} = 3;$$

$$\frac{3}{4}\div\frac{5}{9} = \frac{3}{4}\times\frac{9}{5} = \frac{27}{20} = 1\frac{7}{20};$$

$$3\frac{4}{7}\div 1\frac{2}{3} = \frac{25}{7}\div\frac{5}{3} = \frac{25}{7}\times\frac{3}{5} = \frac{5}{7}\times\frac{3}{1} = \frac{15}{7} = 2\frac{1}{7};$$

$$5\div\frac{7}{8} = 5\times\frac{8}{7} = \frac{40}{7} = 5\frac{5}{7}.$$

(7) A fraction is said to be in its **lowest terms**, or to be **simplified**, when its numerator and denominator have no common factor. Thus,

$$\frac{34}{85}\text{ simplified } = \frac{2}{5}.$$

(8) To reduce to lowest terms. Divide numerator and denominator by their H. C. F. Thus, required the lowest terms of $\frac{34}{85}$.

$$\text{H. C. F. of 34 and 85} = 17;\ \text{and } \frac{34}{85} = \frac{34\div 17}{85\div 17} = \frac{2}{5}.$$

DECIMALS.

(9) Multiplication. The product has as many decimal places as the factors combined. Thus,

Factors: $100 \times 3 \times 3.5 \times 0.004 \times 465.21 = 1953.882000$

Number of decimal places: $0 + 0 + 1 + 3 + 2 = 6$

(10) Division. The number of decimal places in the quotient = those in the dividend minus those in the divisor. Thus,

$$\frac{5.125}{4.1} = 1.25;\ \frac{5}{4} = \frac{5.00}{4} = 1.25;\ \frac{3}{4} = \frac{3.00}{4} = 0.75;\ \frac{0.42}{0.0021} = \frac{0.4200}{0.0021} = 200;$$

When the divisor is a fraction or a mixed number, we may multiply both divisor and dividend by the least power of 10 which will make the divisor a whole number. Thus,

$$\frac{2.679454}{0.0062} = \frac{26,794.54}{62} = 432.17.$$

(11) To reduce a common fraction to decimal form; divide the numerator by the denominator. Thus, $\frac{32}{40} = 0.8$; $1\frac{3}{5} = \frac{8}{5} = 1.6$.

Table 1. Decimal equivalents of common fractions.

8ths	16ths	32ds	64ths		8ths	16ths	32ds	64ths	
			1	.015625				33	.515625
		1	2	.03125			17	34	.53125

			19	.296875				51	.796875
	5	10	20	.3125		13	26	52	.8125
			21	.328125				53	.828125
		11	22	.34375			27	54	.84375
			23	.359375				55	.859375
3	6	12	24	.375	7	14	28	56	.875
			25	.390625				57	.890625
		13	26	.40625			29	58	.90625
			27	.421875				59	.921875
	7	14	28	.4375		15	30	60	.9375
			29	.453125				61	.953125
		15	30	.46875			31	62	.96875
			31	.484375				63	.984375
4	8	16	32	.5	8	16	32	64	1.

(12) To reduce a decimal fraction to common form. Supply the denominator (1), and reduce the resulting fraction to its lowest terms. Thus:

$$0.25 = \frac{0.25}{1.00} = \frac{25}{100} = \frac{1}{4};\quad 0.75 = \frac{75}{100} = \frac{3}{4};\quad 0.890625 = \frac{890625}{1000000} = \frac{57}{64}.$$

(13) **Recurring, circulating, or repeating decimals** are those in which certain digits, or series of digits, recur indefinitely. Thus, $\frac{1}{3} = 0.3333....$, and so on; $\frac{10}{7} = 1.428571428571.....$, and so on. Recurring decimals may be indicated thus: $0.\bar{3}$, $1.\overline{428571}$; or thus: 0.*3, 1.*428571.

RATIO AND PROPORTION.

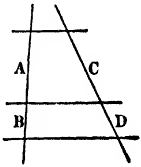
(1) **Ratio.** The ratio of two quantities, as A and B, is expressed by their quotient, $\frac{A}{B}$ or $\frac{B}{A}$. Thus, the ratio of 10 to 5 is $= \frac{10}{5} = 2$; the ratio of 5 to 10 is $= \frac{5}{10} = \frac{1}{2} = 0.5$.

(2) **Duplicate ratio** is the ratio of the *squares* of numbers. Thus, $\frac{A^2}{B^2}$ is the duplicate ratio of A and B.

(3) **Proportion** is equality of ratios. Thus, $\frac{10}{5} = \frac{12}{6} = \frac{1266}{633} = 2$. In the figure, which represents segments, A, B, C, and D, between parallel lines; A : B : : C : D, or $\frac{A}{B} \; \frac{C}{D}$.

(4) The first and fourth terms, A and D, are called the **extremes**, and the second and third, B and C, are called the **means**. The first term, A or C, of each ratio, is called the **antecedent**, and the second term, B or D, is called the **consequent**. D is called the **fourth proportional** of A, B, and C.

(5) In a proportion, A : B = C : D, we have:



Product of extremes = product of means. A D = B C.

Alternation. $\frac{A}{B} = \frac{C}{D}$; $\frac{A}{C} = \frac{B}{D}$.

Inversion. $\frac{B}{A} = \frac{D}{C}$; $\frac{B}{D} = \frac{A}{C}$; $\frac{D}{B} = \frac{C}{A}$.

Composition. $\frac{A+B}{A} = \frac{C+D}{C}$; $\frac{A+B}{B} = \frac{C+D}{D}$.

Division. $\frac{A-B}{A} = \frac{C-D}{C}$; $\frac{A-B}{B} = \frac{C-D}{D}$.

Composition and division. $\frac{A+B}{A-B} = \frac{C+D}{C-D}$.

We have, also:

$$\frac{mA}{mB} = \frac{A}{B} = \frac{C}{D} = \frac{nA}{nB} = \frac{nC}{nD};\quad \frac{mA}{nB} = \frac{mC}{nD};\quad \frac{A^n}{B^n} = \frac{C^n}{D^n};\quad \frac{\sqrt[n]{A}}{\sqrt[n]{B}} = \frac{\sqrt[n]{C}}{\sqrt[n]{D}}.$$

(6) If, in the proportion, A : B = C : D, we have B = C = m, then A : m = m : D, or $\frac{A}{m} = \frac{m}{D}$ or $m^2 = AD$, or $m = \sqrt{AD}$.

(7) In such cases, m is called the **mean proportional** between A and D, and D is called the **third proportional** of A and m.

A continued proportion is a series of equal ratios, as

A : B = C : D = E : F, etc. = R; or $\frac{A}{B} = \frac{C}{D} = \frac{E}{F}$, etc. = R

In continued proportion,

$$\frac{A+C+E+\text{etc.}}{B+D+F+\text{etc.}} = \frac{A}{B} = \frac{C}{D} = \frac{E}{F}\text{ etc.} = R$$

If $\frac{A}{B} = \frac{C}{D}$; $\frac{A'}{B'} = \frac{C'}{D'}$; $\frac{A''}{B''} = \frac{C''}{D''}$; then $\frac{A\,A'\,A''}{B\,B'\,B''} = \frac{C\,C'\,C''}{D\,D'\,D''}$ etc.

(8) Let A, B, and C be any three numbers. Then

$$\frac{A}{C} = \frac{A}{B}\cdot\frac{B}{C} \text{ and } \frac{A}{B} = \frac{A}{C}\cdot\frac{C}{B}.$$

* 0.*3, 1.*428571, etc., standing for 0.3333...., 1.428571428571..... etc.

(9) Reciprocal or inverse proportion. Two quantities are said to be *reciprocally* or *inversely* proportional, when the ratio $\frac{A}{B}$ of two values, A and B, of the one, is = the reciprocal, $\frac{B'}{A'}$, of the ratio of the two corresponding values of the other. Thus, let A = a velocity of 2 miles per hour, and B = 3 miles per hour. Then the *hours required per mile* are respectively, $A' = \frac{1}{A} = \frac{1}{2}$, and $B' = \frac{1}{B} = \frac{1}{3}$. Here $A : B = B' : A'$, or $\frac{A}{B} = \frac{B'}{A'}$, or $\frac{2}{3} = \frac{\frac{1}{3}}{\frac{1}{2}} = \frac{2}{3} = 1 \div \frac{A'}{B'}$.

(10) If two variable numbers, A and B, are reciprocally proportional, so that $A' : B' = B'' : A''$, the product, $A' A''$, of any two values of one of the numbers is equal to the product, $B' B''$ of the two corresponding values of the other.

(11) The application of proportion to practical problems is sometimes called the **rule of three.** Thus: **single rule of three.** If 3 men lay 10,000 bricks in a certain time, how many could 6 men lay in the same time?

As 3 men are to 6 men, so are 10,000 bricks to 20,000 bricks; or, 10,000 bricks $\times \frac{6}{3} = 20{,}000$ bricks.

If 3 men require 10 hours to lay a certain number of bricks, how many hours would 6 men require to lay the same number?

As 6 men are to 3 men, so are 10 hours to 5 hours; or, 10 hours $\times \frac{3}{6} = 5$ hours.

(12) Double rule of three.

If 3 men can lay 4,000 bricks in 2 days, how many men can lay 12,000 bricks in 3 days? Here 4,000 bricks require 3 men 2 days, or 6 man-days, and 12,000 bricks will require $6 \times \frac{12{,}000}{4{,}000} = 6 \times 3 = 18$ man-days; and, as the work is to be done in 3 days, $\frac{18}{3} = 6$ men will be required.

PROGRESSION.

(1) Arithmetical Progression. A series of numbers is said to be in arithmetical progression when each number differs from the preceding one by the same amount. Thus, −2, −1, 0, 1, 2, 3, 4, etc., where difference = 1; or 4, 3, 2, 1, 0, −1, −2, etc., where difference = −1; or −4, −2, 0, 2, 4, 6, 8, 10, where difference = 2; or 1½, 1¼, 1, ¾, ½, ¼, 0, −¼, −½, etc., where difference = −¼.

(2) In any such series the numbers are called terms. Let a be the first term, l the last term, d the common difference, n the number of terms, and s the sum of the terms. Then

Required	Given	
l	$a\ d\ n$	$l = a + (n - 1)\,d$
l	$a\ d\ s$	$l = -\frac{1}{2}d \pm \sqrt{2\,d\,s + (a - \frac{1}{2}d)^2}$
s	$a\ d\ n$	$s = \frac{1}{2}n\left[2\,a + (n - 1)\,d\right]$
a	$d\ l\ s$	$a = \frac{1}{2}d \pm \sqrt{(l + \frac{1}{2}d)^2 - 2\,d\,s}$
n	$a\ d\ s$	$n = \frac{d - 2\,a \pm \sqrt{(2\,a - d)^2 + 8\,d\,s}}{2\,d}$
n	$d\ l\ s$	$n = \frac{2\,l + d \pm \sqrt{(2\,l + d)^2 - 8\,d\,s}}{2\,d}$

(3) Geometrical Progression. A series of numbers is said to be in geometrical progression when each number stands to the preceding one in the same ratio. Thus: $\frac{1}{9}$, $\frac{1}{3}$, 1, 3, 9, 27, 81, etc., where ratio = 3; or 48, 24, 12, 6, 3, $1\frac{1}{2}$, $\frac{3}{4}$, $\frac{3}{8}$, etc., where ratio = $\frac{1}{2}$; or $\frac{27}{32}$, $1\frac{11}{16}$, $3\frac{3}{8}$, $6\frac{3}{4}$, $13\frac{1}{2}$, 27, etc., where ratio = 2.

(4) Let a be the first term, l the last term, r the constant ratio, n the number of terms, and s the sum of the terms. Then:

Required	Given	
l	$a\ r\ n$	$l = a r^{n-1}$*
l	$a\ r\ s$	$l = \dfrac{a + (r-1)s}{r}$
l	$r\ n\ s$	$l = \dfrac{(r-1)s r^{n-1}}{r^n - 1}$
s	$a\ n\ l$	$s = \dfrac{\sqrt[n-1]{l^n} - \sqrt[n-1]{a^n}}{\sqrt[n-1]{l} - \sqrt[n-1]{a}}$
s	$r\ n\ l$	$s = \dfrac{l r^n - l}{r^n - r^{n-1}}$
r	$a\ n\ l$	$r = \sqrt[n-1]{l \div a}$

PERMUTATION, Etc.

(1) **Permutation** shows in how many positions any number of things can be arranged in a row. To do this, multiply together all the numbers used in counting the things. Thus, in how many positions in a row can 9 things be placed? Here,

$$1 \times 2 \times 3 \times 4 \times 5 \times 6 \times 7 \times 8 \times 9 = 362880 \text{ positions. Ans.}$$

(2) **Combination** shows how many combinations of a few things can be made out of a greater number of things. To do this, first set down that number which indicates the greater number of things; and after it a series of numbers, diminishing by 1, until there are *in all* as many as the number of the few things that are to form each combination. Then beginning under the last one, set down said number of few things; and going backward, set down another series, also diminishing by 1, until arriving under the first of the upper numbers. Multiply together all the upper numbers to form one product; and all the lower ones to form another. Divide the upper product by the lower one.

Ex. How many combinations of 4 figures each, can be made from the 9 figures 1, 2, 3, 4, 5, 6, 7, 8, 9, or from 9 any things?

$$\frac{9 \times 8 \times 7 \times 6}{1 \times 2 \times 3 \times 4} = \frac{3024}{24} = 126 \text{ combinations. Ans.}$$

(3) **Alligation** shows the value of a mixture of different ingredients, when the quantity and value of each of these last is known.

Ex. What is the value of a pound of a mixture of 20 lbs of sugar worth 15 cts per lb; with 30 lbs worth 25 cts per lb?

lbs.		cts.		cts.
20	×	15	=	300
30	×	25	=	750
50 lbs.				1050 cts.

Therefore, $\dfrac{1050}{50} = 21$ cts. Ans.

PERCENTAGE, INTEREST, ANNUITIES.

Percentage.

(1) Ratio is often expressed by means of the word "per" Thus, we speak of a grade of 105.6 feet per mile, *i. e.*, per 5280 feet. When the two numbers in the ratio refer to quantities of the same kind and denomination, the ratio is often expressed as a per*centage* (per*hundred*age). Thus, a grade of 105.6 feet per mile,

---

* Equations involving powers and roots are conveniently solved by means of logarithms.

or per 5280 feet, is equivalent to a grade of 0.02 foot per foot,* or 2 feet per 100 feet, or simply (since both dimensions are in feet) 2 per 100, or 2 per "cent."

(2) One-fiftieth, or 1 per 50, is plainly equal to two hundredths, or 2 per *hundred*, or 2 per *cent*. Similarly ¼ = 25 per cent., ¾ = 3 × 25 per cent. = 75 per cent., etc. Hence, to reduce a ratio to the form of percentage, divide 100 times* the first term by the second. Thus, in a concrete of 1 part cement to 2 of sand and 5 of broken stone, there are 8 parts in all, and we have, by weight—†

Cement	$\frac{1}{8}$ = 0.125 =	12.5 per cent. of the whole.			
Sand	$\frac{2}{8}$ = 0.250	25.0	"	"	
Stone	$\frac{5}{8}$ = 0.625	62.5	"	"	
Concrete	$\frac{8}{8}$ = 1.000	100.0	"	"	

(3) Percentage is of very wide application in money matters, payment for service in such matters being often based upon the amount of money involved. Thus, a purchasing or selling agent may be paid a brokerage or commission which forms a certain percentage of the money value of the goods bought or sold; the premium paid for insurance is a percentage upon the value of the goods insured, etc.

Interest.

(4) Interest is hire or rental paid for the loan of money. The sum loaned is called the **principal**, and the number of cents paid annually for the loan of each dollar, or of dollars per hundred dollars, is called the **rate** of interest. The rate is always stated as a percentage.

(5) If the interest is paid to the lender as it accrues, the money is said to be at **simple interest**; but if the interest is periodically added to the principal, so that it also earns interest, the money is said to be at **compound interest**, and the interest is said to be compounded.

Simple Interest.

(6) At the end of a year, the interest on the principal, P, at the rate, r, is = P r, and the **amount**, A, or sum of principal and interest, is

$$A = P + P\,r = P\,(1 + r).$$

(7) At the end of a number, n, of years, the interest is = P r n (see right-hand side of Fig. 1), and

$$A = P + P\,r\,n = P\,(1 + r\,n).$$

Thus, let P = \$865.32, r = 3 per cent., or 0.03, n = 1 year, 3 months and 10 days = 1 year and 100 days = $1\frac{100}{365}$ years = 1.274 years. Then A = P (1 + r n) = \$865.32 × (1 + 0.03 × 1.274) = \$865.32 × 1.03822 = \$898.39.

(8) For the **present worth, principal, or capitalization,** P, of the amount, A, we have

$$P = \frac{A}{1 + r\,n}$$

Thus, for the sum, P, which, in 1 year, 3 months, 10 days, at 3 per cent. simple interest, will amount to \$898.39, we have P = $\frac{898.39}{1 + 0.03 \times 1.274}$ = \$865.32.

(9) In commercial business, interest is commonly **calculated approximately** by taking the year as consisting of 12 months of 30 days each. Then, at 6 per cent., the interest for 2 months, or 60 days, = 1 per cent.; 1 month, or 30 days, = ½ per cent.; 6 days = 0.1 per cent. Thus, required the interest on \$1264.35 for 5 months, 28 days, at 5 per cent.

---

* A *fraction*, as $\frac{1}{8}$, $\frac{5}{16}$, etc., or its decimal equivalent, as 0.125, 0.3125, etc., is compared with *unity* or *one*; but in *percentage* the first term of the ratio is compared with *one hundred* units of the second term. Mistakes often occur through neglect of this distinction. Thus, 0.06 (six per cent. or six per hundred) is sometimes mis-read six one-hundredths of one per cent. or six one-hundredths per cent.

† For proportions by volume, see pp 935 and 943.

Principal		\$1264.35
Interest, 2 mos,	1 per cent	12.64
" 2 mos,	1 "	12.64
" 1 mo,	$\frac{1}{2}$ "	6.32
" 20 days,	$\frac{1}{3}$ "	4.21
" 6 days,	0.1 "	1.26
" 2 days,	$\frac{1}{30}$ "	0.42
Interest at 6 per cent		\$37.49
Deduct one-sixth		6.25
Interest at 5 per cent		\$31.24

Equation of Payments.

(10) A owes B \$1200; of which \$400 are to be paid in 3 months; \$500 in 4 months; and \$300 in 6 months; all bearing interest until paid; but it has been agreed to pay all at once. Now, at what time must this payment be made so that neither party shall lose any interest?

\$		months.		
400	×	3	=	1200
500	×	4	=	2000
300	×	6	=	1800
1200				5000

Average time $= \frac{5000}{1200} = 4\frac{1}{6}$ months. Ans.

Compound Interest.

(11) Interest is usually compounded annually, semi-annually, or quarterly. If it is compounded annually, then (see left side of Fig. 1)

at the end of 1 year $A = P(1+r)$

" " 2 years $A = P(1+r)(1+r) = P(1+r)^2$

" " n years $A = P(1+r)^n$; and

$$P = \frac{A}{(1+r)^n} = A(1+r)^{-n}$$

$$\frac{A}{P} = (1+r)^n$$

(12) If the interest is compounded q times per year, we have

$$\frac{A}{P} = \left(1 + \frac{r}{q}\right)^{qn}$$

(13) The principal, P, is sometimes called the **present worth** or **present value** of the amount, A. Thus, in the following table, \$1.00 is the present worth of \$2.191 due in 20 years at 4 per cent. compound interest, etc etc.

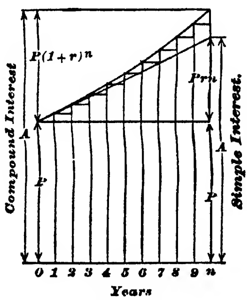


Fig. 1.

Table 2. Compound Interest.

Amount of $1 at Compound Interest.

Years.	3 per cent.	3½ per cent.	4 per cent.	4½ per cent.	5 per cent.	5½ per cent.	6 per cent.	6½ per cent.

Compound interest on M dollars, at any rate r for n years = M × compound interest on $1 at same rate, r, and for n years.

Annuity, Sinking Fund, Amortization, Depreciation.

(14) Under "Interest" we deal with cases where a certain sum or "principal," P, paid once for all, is allowed to accumulate either simple or compound interest; but in many cases equal periodical payments or appropriations, called **annuities**, are allowed to accumulate, each earning its own interest, usually compound.

(15) Thus, a sum of money is set aside annually to accumulate compound interest and thus form a **sinking fund**, in order to extinguish a debt. In this way, the cost of engineering works is frequently paid virtually in instalments. This process is called **amortization.**

(16) In estimating the operating expenses of engineering works, an allowance is made for **depreciation.** In calculating this allowance, we estimate or assume the life-time, n, of the plant, and find that annuity, p, which, at an assumed rate, r, of compound interest, will, in the time n, amount to the cost of the plant, and thus provide a fund by means of which the plant may be replaced when worn out or superseded.

(17) The **present worth, present value,** or **capitalization,** W, Fig. 2, of an annuity, p, for a given number, n, of years, is that sum which, if now placed at compound interest at the assumed rate, r, will, at the end of that time, reach the same amount, A, as will be reached by that annuity.

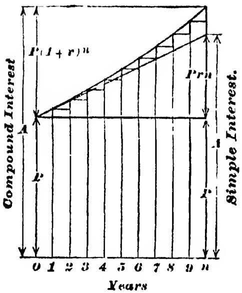

Fig. 1.

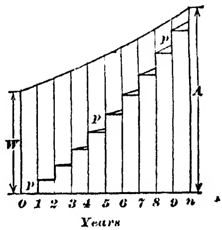

Fig. 2.

(18) Equations for Compound Interest and Annuities. (See Figs. 1 and 2.)

P = principal; r = rate of interest; n = number of years;
A = amount; p = annuity; W = present worth.

The interest is supposed to be compounded, and the annuities to be set aside, at the *end* of each year.

Compound Interest.

(1) **The amount, A,** *of \$1, at the end of n years, see* **(11)**, *is* $A = (1+r)^n$.

(2) Since the present worth of $(1+r)^n$, due in n years, is \$1, see (1), it follows, by proportion, that **the present worth, W,** of \$1, due in n years, is $W = \dfrac{1}{(1+r)^n} = (1+r)^{-n}$.

Annuities.

(3) In n years, an annuity of \$$r$ will amount to $(1+r)^n - 1$.* Hence, the **amount, A, of an annuity** of \$1, at the end of n years, is

$$A = \frac{(1+r)^n - 1}{r}.$$

---

*In the case of compound interest on \$1, the rate, r, may be regarded as an annuity, earning its interest; and, at the end of n years, the amount of the several annuities (each = the annual interest, r, on the \$1 principal) with the interests earned by them, is = the amount, $(1+r)^n$, of \$1 in n years at rate, r, minus the \$1 principal itself; or, amount of annuity = $(1+r)^n - 1$.

(4) For **the present worth, W, of an annuity** of \$1 for n years, we have, from Equations (1) and (3):

$$(1+r)^n : 1 = \frac{(1+r)^n - 1}{r} : \mathrm{W}. \quad \text{Hence, } \mathrm{W} = \frac{(1+r)^n - 1}{(1+r)^n\, r} = \frac{1 - \dfrac{1}{(1+r)^n}}{r}$$

See Table 3.

(5) The annuity for n years, which \$1 will purchase, is

$$p = \frac{1}{\mathrm{W}}* = \frac{r}{1 - \dfrac{1}{(1+r)^n}}$$

(6) The annuity which, in n years, will amount to \$1, is

$$p' = p - r = \frac{1}{\mathrm{W}} - r = \frac{r}{1 - \dfrac{1}{(1+r)^n}} - r = \frac{r}{(1+r)^n - 1}\dagger$$

See Table 4.

Table 3. Present Value of Annuity of \$1000. See Equation (4).

	Rate of Interest (Compound).							
Years.	2½ per cent.	3 per cent.	3½ per cent.	4 per cent.	4½ per cent.	5 per cent.	5½ per cent.	6 per cent.
5	4,646	4,580	4,515	4,452	4,390	4,329	4,268	4,212

40	25,103	23,115	21,355	19,793	18,401	17,159	16,045	15,046
45	26,833	24,519	22,495	20,720	19,156	17,774	16,548	15,456
50	28,362	25,730	23,456	21,482	19,762	18,256	16,932	15,762
100	36,614	31,599	27,655	24,505	21,950	19,848	18,096	16,618

(19) In comparing the merits of proposed systems of improvement, it is usual to add, to the operating expenses and to the cost of ordinary repairs and maintenance, (1) the interest on the cost, (2) an allowance for depreciation, and sometimes (3) an annuity to form a sinking fund for the extinction of the debt incurred by construction. The capitalization of the total annual expense, thus obtained, is then *regarded as the true first cost of the construction. All* the elements of cost are thus reduced to a common basis, and the several propositions become properly comparable.

(20) Thus, in estimating, in 1899,‡ the cost of improving the water supply of Philadelphia, the rate, r, of interest was assumed at 3 per cent, and depreciation was assumed as below. Under "Life" is given the assumed life-time of each class of structure or apparatus, and under "Annuity" the sum which must be set aside annually in order to replace, at the expiration of that life, \$1,000 of the corresponding value.

---

* Because, $\underset{\text{Equation (4)}}{\overset{\text{Present worth}}{\mathrm{W}} : \overset{\text{Annuity}}{\$1.00}} \;::\; \underset{\text{Equation (5)}}{\overset{\text{Present worth}}{\$1.00} : \overset{\text{Annuity}}{p}}$. Hence, $p = \dfrac{1}{\mathrm{W}}$.

† Because, $\underset{\text{Equation (3)}}{\overset{\text{Annuity}}{r} : \overset{\text{Amount}}{(1+r)^n - 1}} \;::\; \underset{\text{Equation (6)}}{\overset{\text{Annuity}}{p'} : \overset{\text{Amount}}{\$1.00}}$. Hence, $p' = \dfrac{r}{(1+r)^n - 1}$.

‡ Report by Rudolph Hering, Samuel M. Gray and Joseph M. Wilson.

Structures, Apparatus, etc.	Life, in years	Annuity $
Masonry conduits, filter beds, reservoirs	Indefinite	0.00
Permanent buildings	100	1.65
Cast iron pipe, railroad side-tracks	80	3.11
Steel pipe, valves, blow-offs, and gates	35	16.54
Engines and pumps	30	21.02
Boilers, electric light plants, tramways and equipment, iron fences	20	37.22
Telephone lines, sand-washer, and regulating apparatus	10	87.24

(**21**) Calculated upon this basis, two projects, each designed to furnish 450 million gallons per day, compared as follows.

Unfiltered Water, by Aqueduct.

First Cost.

Storage reservoirs		$30,900,000
Aqueducts		47,730,000
Distribution		3,555,000
Distributing reservoir		1,000,000
Total		$83,185,000

Annual.

Interest on $83,185,000		$2,495,550
Depreciation		198,640
Operation and Maintenance.		
Analyses and inspection	$41,620	
Ordinary repairs	49,150	
Pumping and wages	140,770	
		231,540
		$2,925,730

River Water, taken within City Limits and Filtered.

First Cost.

Filter plants		$23,174,680
Mains		10,980,000
Total		$34,154,680

Annual.

Interest on $34,154,680		$1,024,640
Depreciation		205,540
Operation and Maintenance.		
Pumping	$1,216,021	
Filtration	525,600	
		1,741,621
		$2,971,801

It will be noticed that, although the first cost of the filtration project was much less than half that of the aqueduct project, its large proportion of perishable parts made its charge for depreciation somewhat greater, while its cost for operation and maintenance was more than seven times as great, and its total annual charge a little greater.

Table 4. Annuity required to redeem $1000. See Equation (6).

DUODENAL OR DUODENARY NOTATION.*

(1) In the Arabic system of notation 10 is taken as the base, but in duodenal notation 12, or "a dozen," is the base. While 10 is divisible only by 5, and (once only) by 2, 12 is divisible twice by 2, and once by 3, by 4, and by 6. This accounts for the popularity of the dozen as a basis of enumeration; of weights, as in the Troy pound of 12 ounces; of measures, as in the foot of 12 inches; the year of 12 months, and the half day of 12 hours; and of coinage, as in the British shilling of 12 pence.

(2) The duodenal notation uses the dozen (12), the gross ($12^2 = 144$), and the great gross ($12^3 = 12$ gross $= 1728$), as the decimal system uses the ten (10), the hundred ($10^2 = 100$), and the thousand ($10^3 = 10$ hundred $= 1000$). Two arbitrary single characters, such as T and E, represent ten and eleven respectively; the symbol 10 represents a dozen; 11 represents thirteen, and so on. Thus, the numerals of the two systems compare as follows:

Decimal	1	2	3	4	5	6	7	8	9	10	11	12	13	14	...	20	21	22	23	24	25	36	48	60
Duodenal	1	2	3	4	5	6	7	8	9	T	E	10	11	12	...	18	19	1T	1E	20	21	30	40	50

Decimal	72	84	96	99	100	108	109	110	111	112	113	117	118	119	120	121	122
Duodenal	60	70	80	83	84	90	91	92	93	94	95	99	9T	9E	T0	T1	T2

Decimal	129	130	131	132	133	138	140	141	142	143	144	288	1728	20736	etc.
Duodenal	T9	TT	TE	E0	E1	E6	E8	E9	ET	EE	100	200	1000	10000	etc.

(3) Duodecimals. Areas of rectangular figures, the sides of which are expressed in feet and inches, are still sometimes found by a method called "Duodecimals," in which the products are in square feet, in twelfths of a square foot (each equal to 12 square inches) and in square inches; but, by means of our table of "Inches, reduced to decimals of a foot," page 221, the sides may be taken in feet and decimals of a foot, and the multiplication thus more conveniently performed, after which the decimal fraction of a foot in the product may, if desired, be converted into square inches by multiplying by 144.

*See Elements of Mechanics, by the late John W. Nystrom.

RECIPROCALS.

(**a**) **The reciprocal of a number is** the quantity obtained by dividing unity or 1 by that number. In other words, if n be any number, then Recip $n = \frac{1}{n}$. Thus, Recip 40 $= \frac{1}{40} = 0.025$, Recip 0.4 $= \frac{1}{0.4} = 2.5$, etc., etc.

Hence, Recip $\frac{a}{b} = \frac{b}{a}$, because Recip $\frac{a}{b} = 1 \div \frac{a}{b} = 1 \times \frac{b}{a} = \frac{b}{a}$.

Thus, since 1 yard = 36 inches, 1 inch = $\frac{1}{36}$ yard = .027777778 yard, for Recip 36 = .027777778. Again, 1 foot head of water gives a pressure of .4335 lbs. per square inch. Hence a pressure of 1 lb per square inch corresponds to a head of $\frac{1}{.4335}$ feet = 2.306805 feet, for Recip .4335 = 2.306805. (See **h**, below.)

(**b**) It follows that if any number in the column headed "No." be taken as the denominator of a common fraction whose numerator is 1, the corresponding reciprocal is the value of that fraction expressed in decimals.* Thus, $\frac{1}{32}$ = .03125. Hence, **to reduce a common fraction to decimal form,** multiply the reciprocal of the denominator by the numerator. Thus, $\frac{17}{32}$ = .53125, because Recip 32 = .03125, and .03125 × 17 = .53125.

(**c**) Conversely, if the reciprocal of a number n be taken as a number, then the number n itself becomes the reciprocal. In other words, Recip $\frac{1}{n} = n$. Thus, Recip 0.025 = Recip $\frac{1}{40}$ = 40; Recip 2.5 = Recip $\frac{1}{0.4}$ = 0.4, etc., etc.

* The numbers 2 and 5, and their powers and products, are the only ones whose reciprocals can be *exactly* expressed in decimals.

(d) The product of any number by its own reciprocal is equal to unity or 1; or, $n \times \frac{1}{n} = \frac{n}{n} = 1$.

(e) Any number, $a \times$ Recip of a number, $n = a \times \frac{1}{n} = \frac{a}{n}$.

Hence, **to avoid the labor of dividing,** we may *multiply* by the *reciprocal* of the divisor. Thus,
$200 \div 48750 = 200 \times$ Recip $48750 = 200 \times .0000205128$ (see **h.** below) $= .004102564\ldots$

(f) Any number, $a \div$ Recip of a number, $n = a \div \frac{1}{n} = a\,n$.

Hence, $\quad a \div$ Recip $a = a \div \frac{1}{a} = a \times \frac{a}{1} = a^2$

Thus $\quad$ Recip $2 = 0.5$, and $\frac{2}{\text{Recip } 2} = \frac{2}{0.5} = 4 = 2^2$.

(g) The numbers in the foregoing table extend from 1 to 1000, but the reciprocals of **multiples of these numbers by 10** may be taken from the table by adding one cipher to the left of the reciprocal (after the decimal point) for each cipher added to the number. Thus,

Recip 390 = .002564103,
Recip 3900 = .0002564103;
Recip 39000 = .00002564103;

and the reciprocals of **numbers containing decimals** may be taken from the table by shifting the decimal point in the tabular reciprocal one place to the right for each decimal place in the number. Thus,

Recip 227 = .004405286;
Recip 22.7 = .04405286;
Recip 2.27 = .4405286,
Recip .227 = 4.405286;
Recip .0227 = 44.05286.

(h) The reciprocal of a **number of more than three figures** may be taken from the table approximately by interpolation. Thus, to find Recip 236.4:

Recip 236 = .004237288
Recip 237 = .004219409

Differences: 1, .000017879, $236.4 - 236 = 0.4$.
Then, $0.4 \times .000017879 = .000007152$,

and Recip 236 = .004237288
minus .000007152

= Recip 236.4 = .004230136 by interpolation.

The correct reciprocal is .004230118.

(i) The reciprocals of numbers not in the table may be conveniently found **by means of logarithms.** Thus, to find the Recip $236.4 = \frac{1}{236.4}$:

Log 1 = 0.000000
Subtract Log 236.4 = 2.373647

$\bar{3}.626353$ = Log 0.00423012
Recip 236.4 = 0.00423012.

To find Recip $\frac{8424}{236.4} = \frac{236.4}{8424}$,

Log 236.4 = 2.373647
Subtract Log 8424 = 3.925518

$\bar{2}.448129$ = Log 0.0280627.
Recip $\frac{8424}{236.4} = 0.0280627$.

(j) Position of the decimal point. For the Nos 10, 100, 1000, etc., the number of the decimal place occupied by the first significant figure in the reciprocal is equal to the number of *ciphers* in the No; but for all other Nos it is equal to the number of the *digits* in the integral portion of the No. Thus: Recip 143.7 = .0069..., etc. Here the number of digits in the integral portion (143) of the No. is 3, and the first significant figure (6) of the reciprocal occupies the *third* decimal place.

Square Roots and Cube Roots of Numbers from .1 to 28.

TABLE of Squares, Cubes, Square Roots, and Cube Roots, of Numbers from 1 to 1000.

REMARK ON THE FOLLOWING TABLE. Wherever the effect of a fifth decimal in the roots would be to add 1 to the fourth and final decimal in the table, the addition has been made. No errors.

To find the square or cube of any whole number ending with ciphers. First, omit all the final ciphers. Take from the table the square or cube (as the case may be) of the rest of the number. To this *square* add *twice* as many ciphers as there were final ciphers in the original number. To the *cube* add *three* times as many as in the original number. Thus, for 90500^2; $905^2 = 819025$. Add twice 2 ciphers, obtaining 8190250000. for 90500^3 $905^3 = 741217625$. Add 3 times 2 ciphers, obtaining 741217625000000.

Square Roots and Cube Roots of Numbers from 1000 to 10000.

No errors.

To find Square or Cube Roots of large numbers not contained in the column of numbers of the table.

Such roots may sometimes be taken at once from the table, by merely regarding the columns of powers as being columns of numbers; and those of numbers as being those of roots. Thus, if the *sq rt* of 25281 is reqd, first find that number in the column of *squares;* and opposite to it, in the column of numbers, is its sq rt 159 For the *cube rt* of 857375, find that number in the column of *cubes;* and opposite to it, in the col of numbers, is its cube rt 95. When the exact number is not contained in the column of squares, or cubes, as the case may be, we may use instead the number nearest to it, if no great accuracy is reqd But when a considerable degree of accuracy is necessary, the following very correct methods may be used.

For the square root.

This rule applies both to whole numbers, and to those which are *partly* (not wholly) decimal First, in the foregoing manner, take out the tabular number, which is nearest to the given one; and also its tabular sq rt. Mult this tabular number by 3, to the prod add the given number. Call the sum A. Then mult the given number by 3, to the prod add the tabular number. Call the sum B. Then

A : B : : Tabular root : Reqd root.

Ex. Let the given number be 946 53. Here we find the nearest tabular number to be 947; and its tabular sq rt 30.7734 Hence,

$$\left.\begin{array}{l} 947 = \text{tab num} \\ \quad 3 \\ \hline 2841 \\ 946.53 = \text{given num.} \\ \hline 3787.53 = \text{A.} \end{array}\right\} \text{ and } \left\{\begin{array}{l} 946.53 = \text{given num.} \\ \quad 3 \\ \hline 2839\ 59 \\ 947 \quad = \text{tab num.} \\ \hline 3786.59 = \text{B.} \end{array}\right.$$

	A.		B.		Tab root.		Reqd root.
Then	3787.53	:	3786.59	: :	30.7734	:	30.7657 +.

The root as found by actual mathematical process is also 30.7657 +.

For the cube root.

This rule applies both to whole numbers, and to those which are *partly* decimal. First take out the tabular number which is nearest to the given one; and also *its* tabular cube rt. Mult this tabular number by 2; and to the prod add the given number Call the sum A. Then mult the given number by 2; and to the prod add the tabular number. Call the sum B. Then

A : B : : Tabular root : Reqd root.

Ex. Let the given number be 7368. Here we find the nearest tabular number (in the column of cubes) to be 6859; and its tabular cube rt 19. Hence,

$$\left.\begin{array}{l} 6859 = \text{tab num.} \\ \quad 2 \\ \hline 13718 \\ 7368 = \text{given num.} \\ \hline 21086 = \text{A.} \end{array}\right\} \text{ and } \left\{\begin{array}{l} 7368 = \text{given num.} \\ \quad 2 \\ \hline 14736 \\ 6859 = \text{tab num.} \\ \hline 21595 = \text{B.} \end{array}\right.$$

	A.		B.		Tab Root.		Reqd Rt.
Then, as	21086	:	21595	: :	19	:	19 4585

The root as found by correct mathematical process is 19.4588. The engineer rarely requires even

this degree of accuracy; for his purposes, therefore, this process is greatly preferable to the ordinary laborious one.

To find the square root of a number which is wholly decimal.

Very simple, and correct to the third numeral figure inclusive. If the number does not contain at least five figures, *counting from the first numeral, and including it*, add one or more ciphers to make five If, after that, the *whole number* is not separable into twos, add another cipher to make it so. Then beginning at the first numeral figure, and including it, assume the number to be a whole one. In the table find the number nearest to this assumed one, take out its tabular sq rt, move the decimal point of this tabular root to the left, *half* as many places as the finally modified *decimal* number has figures.

Ex. What is the sq rt of the decimal 002? Here, in order to have at least five decimal figures, counting from the first numeral (2), and including it, add ciphers thus, 00 20,00 0. But, as it is not now separable into twos, add another cipher, thus, .00,20,00,00 Then beginning at the first numeral (2), assume this decimal to be the whole number 200000. The nearest to this in the table is 199809; and the sq rt of this is 447 Now the decimal number as finally modified, namely, 00,20,00,00, has eight figures, one half of which is 4, therefore, move the decimal point of the root 447, four places to the left, making it .0447 This is the reqd sq rt of 002, correct to the third numeral 7 included.

To find the cube root of a number which is wholly decimal.

Very simple, and correct to the third numeral inclusive

If the number does not contain at least five figures, counting from the first numeral, and including it, add one or more ciphers to make five If, after that, the number is not separable into threes, add one or more ciphers to make it so. Then beginning at the first numeral, and including it, assume the number to be a whole one. In the table find the number nearest to this assumed one, and take out its tabular cub rt Move the decimal point of this rt to the left, one third as many places as the finally modified *decimal* number has figures

Ex What is the cube rt of the decimal 002? Here, in order to have at least five figures, counting from the first numeral (2), and including it, add ciphers thus, 002 000 0 But as it is not now separable into threes, add two more ciphers to make it so, thus 002,000,000 Then beginning with the first numeral (2), assume the decimal to be the whole number 2000000 The nearest cube to this in the table in the column of cubes, is 2000376, and its tabular cube rt as found in the col of numbers is 126 Now, the decimal number as finally modified namely, 002 000 000, has nine figures; one-third of which is 3, therefore, move the decimal point of the root 126, three places to the left, making it .126. This is the reqd cube rt of the decimal .002, correct to the third numeral 6 included.

Square roots of fifth powers of numbers, $\sqrt{n^5}$,

or $5/2$ powers of numbers, $n^{5/2}$.

See table, page 69.

The column headed "12 n" facilitates the use of the table in cases where, for instance, the quantity is given in *inches*, and where it is desired to obtain the $5/2$ power of the same quantity in *feet*. Thus, suppose we have a $1/2$ inch pipe, and we require the $5/2$ power of the diameter in feet. Find $1/2$ (the diameter, in inches) in the column headed "12 n," opposite which, in the column headed "n," is 0.041666 (the diameter, in feet), and, in column headed "$n^{5/2}$," 0.00035 (the $5/2$ power of the diameter, 0.041666, in feet).

Values of n, ending in 0 or in 5, are *exact* values. All others end in repeating decimals. Thus: n = 0.052083 signifies n = 0.0520833333 . . . . .

Square roots of fifth powers of numbers. See page 65.

Logarithms.

(**1**) Tables of logarithms greatly facilitate multiplication and division and the finding of powers and roots of numbers.*

(**2**) The tables pp. 78 to 91 contain the **common, decimal** or **Briggs logarithms** of numbers. The *common* logarithm of a number is the exponent or index of that number as a power of 10. See (18). Thus: $1000 = 10^3$, and log 1000 (logarithm of 1000) = 3 00 000. Similarly, $28.7 = 10^{1.45\ 788}$, and log 28.7 = 1.45 788.

(**3**) In general, let A and B be any two numbers, and k any exponent. Then, from the principle of powers and roots, we have

$$(1)\ \log AB = \log A + \log B; \qquad (2)\ \log \frac{A}{B} = \log A - \log B;$$

$$(3)\ \log A^k = k\,(\log A); \qquad (4)\ \log \sqrt[k]{A} = \frac{\log A}{k}$$

In other words:—
(1) Log of product = sum of logs of factors.
(2) Log of quotient = log of dividend — log of divisor.
Or log of fraction = log of numerator — log of denominator.
(3) Log of power = log of number, multiplied by exponent.
(4) Log of root = log of number, divided by exponent.

(**4**) From what has been said, it follows that

Log 100	=	log 10^2	=	2.00 000	Log 0.1	=	log 10^{-1}	=	$\bar{1}$.00 000†
Log 10	=	log 10^1	=	1.00 000	Log 0.01	=	log 10^{-2}	=	$\bar{2}$.00 000
Log 1	=	log 10^0	=	0.00 000†	Log 0.001	=	log 10^{-3}	=	$\bar{3}$.00 000

(**5**) Each common logarithm is a mixed number, consisting of an *integral* portion, called the **characteristic** or **index** (*preceding* the decimal point), and a *fractional* portion, called the **mantissa** (*following* the decimal point). The table gives only the *mantissa* of each log, the characteristic being found as explained below. The *mantissa* is always *positive*. The characteristic is equal to the number of the place of the first significant figure in the number, counting from the *unit* place as *zero*, and is positive for whole or mixed numbers, and negative for fractions. Thus:

$$\log \underset{4\,3\,2\,1\,0}{2\,4\,6\,0\,0} = 4.39\ 094; \quad \log \underset{0\ \ 1\,2\,3\,4\,5}{0\,.\,0\,0\,0\,0\,4} = \bar{5}.60\ 206.$$

For example:

log 2870 = 3.45 788		log 0.287 = $\bar{1}$.45 788‡	
" 287 = 2.45 788		" 0.0287 = $\bar{2}$.45 788	
" 28.7 = 1.45 788		" 0.00287 = $\bar{3}$.45 788	
" 2.87 = 0.45 788		" 0.000287 = $\bar{4}$.45 788	

It will be noticed that the mantissa remains constant for any given combination of significant figures in a number, wherever the decimal point in the number be placed; while the characteristic depends solely upon the position of the decimal point in the number.

(**6**) Let the number be resolved into two factors, one of which is an integer power of 10, while the other is greater than 1 and less than 10. Then the index of the power of 10 is the characteristic of the logarithm, and the logarithm of the other factor is the mantissa. Thus, $2870 = 1000 \times 2.87 = 10^3 \times 2.87$, and the logarithm of 2870 (3.45 788) is the sum of the exponent 3 (or 3.00 000) and the log (0.45 788) of 2.87.‡

---

* Logarithms not being exact quantities, operations performed with them are subject to some inaccuracy, especially where a logarithm is multiplied by a large number, the existing error being thus magnified. Logarithms of only five places in the mantissa usually suffice for calculations with numbers of four or five places. Greater accuracy is obtained by the use of tables of logarithms carried out to seven places.

† Log 1 = log $\frac{10}{10}$ = log 10—log 10 = 1—1 = 0; or $1 = 10^0$.

Log 0.1 = log $\frac{1}{10}$ = log 1 — log 10 = 0 — 1 = $\bar{1}$.0; or $0.1 = 10^{-1}$.

‡ 0 287 = 2.87 ÷ 10. Hence, log 0.287 = log 2.87 − log 10 = 0.45 788 − 1, which, for convenience, is written $\bar{1}$.45 788. See (16). Similarly, log 0.0287 = log 2.87 − log 100 = 0.45 788 − 2 = $\bar{2}$.45 788

(7) To find the logarithm of a number. The short table on pages 78, 79 gives logs of numbers up to 1000. The longer table, pages 80 to 91, gives

(1) The mantissa for *each* number from	1000 to 1750
(2) The mantissa for each *even* number from	1750 to 3750
(3) The mantissa for each *fifth* number from	3750 to 10000

(8) Logs of **numbers intermediate** of those given in the tables are found by simple proportion. The procedure necessary in these cases is explained in the examples given in connection with the tables, but it will often be found sufficiently accurate to use the log of the nearest number given in the table, neglecting interpolation.

The antilogarithm, formerly called the **num log** (*numerus logarithmi*), is the **number corresponding** to a given logarithm. Thus, log. 2 = 0.30 103, and antilog 0.30 103 = 2. Usually written: "log $^{-1}$ 0.30 103 = 2."

(9) Multiplication. To multiply together two or more numbers, add together their logs and find the antilog of their sum. See Proportion (11) below.

(10) Division. Subtract the log of the divisor from that of the dividend, and find the antilog of the remainder. See Proportion (11) below.

The **reciprocal** of any number, n, $= \frac{1}{n}$. See page 52. Thus, recip 2 = $\frac{1}{2}$ = 0.5. Hence, log recip n = $\log \frac{1}{n} = \log 1 - \log n = 0 - \log n$.

Similarly, log recip $\frac{m}{n} = \log \frac{1}{m \div n} = 0 - \log \frac{m}{n}$.

Thus, $\log \frac{6.3023}{23057} = 0 - \log \frac{23057}{6.3023} = 0 - 3.56\ 331 = \bar{4}.43\ 669.$

Since $n^{2-1} = n^1 = \frac{n^2}{n}$, $n^{1-1} = n^0 = \frac{n}{n} = 1$, $n^{0-1} = n^{-1} = \frac{1}{n}$, and $n^{0-2} = n^{-2} = \frac{1}{n^2}$ it follows that $\log n^{-1} = \log \frac{1}{n}$ = log recip n, $\log n^{-2} = \log \frac{1}{n^2}$ = log recip n^2, etc.

(11) Proportion. Example. 6.3023 : 290.19 = 1260.7 : ?

Multiply Nos,	Log 290.19	= 2.46 269
Add Logs.	" 1260.7	= 3.10 062
	Log 290.19 × 1260.7	= 5.56 331
Divide Nos,	Log 6.3023	= 0.79 950
Subtract Log.	Log 58051	= 4.76 381

The true value is 58019.05 +

(12) Instead of subtracting the log of the divisor, we may add its **cologarithm** or **arithmetical complement,** which is log of reciprocal of divisor, = 0 — log divisor = 10 — log divisor — 10. Thus:

$$\frac{1523}{3.332 \times 8.655} = ?$$

Log 1523	= 3.18 270
Colog 3.332 = 10 — log 3.332 — 10 = 10 — 0.52 270 — 10	= 9.47 730 — 10
Colog 8.655 = 10 — log 8.655 — 10 = 10 — 0.93 727 — 10	= 9.06 273 — 10
Sum of logs and cologs	= 21.72 273 — 20
	= Log 52.813 = 1.72 273

The true value is 52.8114 +

(13) Involution, or finding powers of numbers. Multiply log of given number by the exponent of the required power, and find the antilog of the product. Thus: $36^3 = ?$

Log 36 = 1.55 630. 1.55 630 × 3 = 4.66 890. Antilog 4.66 890 = 46656.

(14) Evolution, or finding roots of numbers. Divide log of given number by exponent of required root, and find antilog of quotient. Thus: $\sqrt[3]{46656} = ?$ Log 46656 = 4.66 890. 4.66 890 ÷ 3 = 1.55 630. Antilog 1.55 630 = 36.

(15) Involution and evolution of fractions. Negative characteristics. See page 72.

Examples. Required: (1) 0.48^3; (2) $\sqrt[3]{0.48} = 0.48^{1/3}$.

Log $0.48 = \log(48/100) = \log 48 - \log 100 = 1.68\,124 - 2 = 2.68\,124 - 3 = -0.31\,876 = 0.68\,124 - 1$; usually written $\bar{1}.68\,124$.

(1) $\text{Log } 0.48^3 = 3 \log 0.48 = 3(-0.31\,876) = 3(0.68\,124 - 1)$
$= -0.95\,628 \qquad = 2.04\,372 - 3$

Each $= \bar{1}.04\,372$. The corresponding No. is 0.1106. $0.48^3 = 0.1106$.

(2) $\text{Log } 0.48^{1/3} = (\log 0.48)/3 = (0.68\,124 - 1)/3 = (2.68\,124 - 3)/3$
$= (-0.31\,876)/3 = 0.22\,708 - 0.33\,333 = 0.89\,375 - 1$
$= -0.10\,625 \qquad = -0.10\,625 = \bar{1}.89\,375$

Each $= \bar{1}.89\,375$. The corresponding No. is 0.7830. $\sqrt[3]{0.48} = 0.7830$.

(**16**) To avoid inconvenience from the use of **negative characteristics**, it is customary to **modify** them by adding 10 to them, afterward deducting each such 10 from the sum, etc., of the logarithms. Thus: in multiplying or dividing 7425 by 0.25, we have

		Multiplying	Dividing
either	log 7425	3.87 070	3.87 070
	log 0.25	$\bar{1}.39\,794$	$\bar{1}.39\,794$
		3.26 864	4.47 276
or	log 7425	3.87 070	3.87 070
	modified log 0.25	9.39 794 − 10	9.39 794 − 10
		13.26 864 − 10	6.47 276 + 10
		3.26 864	4.47 276

In most cases the actual process of deducting the added tens may be neglected, the nature of the work usually being such that an error so great as that arising from such neglect could hardly pass unnoticed.

(**17**) **To divide a modified logarithm**, add to it such a multiple of 10 as will make the sum exceed the true log by 10 times the divisor. Thus: to divide log 0.00048 by 3. Log 0.00048 = $\bar{4}.68\,124$, which, divided by 3, = $\bar{2}.89\,375$. See (15).

Log 0.00048	= $\bar{4}.68\,124$	
Modified log 0.00048	= 6.68 124	− 10
Add 2 × 10	20	− 20
Dividing by	3) 26.68 124	− 30
we obtain	8.89 375	− 10, which is $\bar{2}.89\,375$ modified.

(**18**) Except 1, any number can (like 10) be made the base of a system of logarithms. The base of the **hyperbolic**, **Napierian**, or **natural logarithms**, much used in steam engineering, is

$$1 + \frac{1}{1} + \frac{1}{1 \times 2} + \frac{1}{1 \times 2 \times 3} + \frac{1}{1 \times 2 \times 3 \times 4} + \ldots = 2.71\,828 +$$

and is called ϵ (epsilon) or e.

$M = \log_{10} e$ (common log e) $= 0.43\,429$; $\frac{1}{M} = \log_e 10$ (hyperbolic log 10) $= 2.30\,259$.

For any number, n,

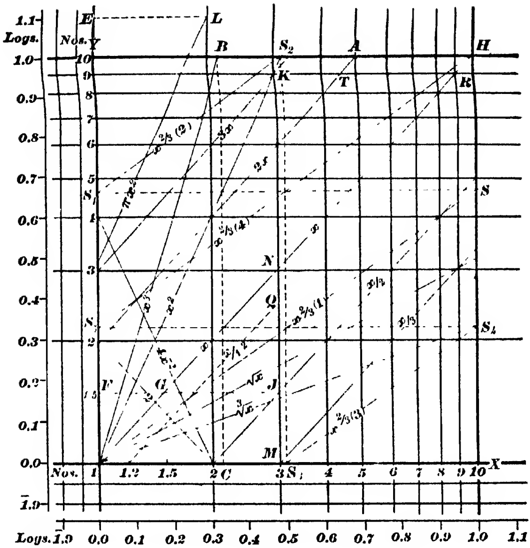
$$\log_e n = \frac{\log_{10} n}{M} = 2.30259 \log_{10} n; \quad \log_{10} n = M \log_e n = 0.43429 \log_e n$$

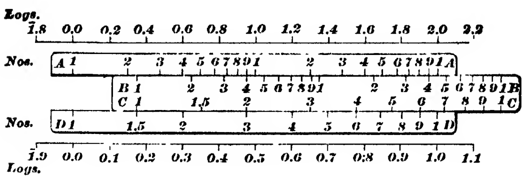
(**19**) Whatever may be the base chosen for a system of logs, the **mantissas** of the logs of any given numbers bear a **constant ratio** to each other. Thus, in any system of logs, log 4 is always $= 2 \times \log 2$, and $= \frac{2}{3} \times \log 8$, etc., etc.

(**20**) **Logarithmic sines, tangents**, etc. of angles are the logs of the sines, tangents, etc. of those angles. Thus, sin 30° = 0.5000000, and log sin 30° = log. 0.5 = $\bar{1}.69\,897$, usually written 9.69 897 − 10, or simply 9.69 897.

For tables of logarithmic sines, tangents, etc., see pp. 1029, etc.

(**21**) Since no power of a positive number can be negative, negative numbers properly have no logs; but **operations with negative numbers** can nevertheless be performed by means of logs, by treating all the numbers as positive and taking care to use the proper sign, + or −, in the result. Thus: required the 3rd power of (−2). Log 2 = 0.30 103; and $3 \times 0.30\,103 = 0.90\,309 = \log 8$; but $(-2)^3$ must be negative. Hence $(-2)^3 = -8$.





The Logarithmic Chart and the Slide Rule.

(1) By means of a logarithmic chart or diagram (often miscalled logarithmic cross-section paper) logarithmic operations are performed graphically, and by means of the slide rule mechanically, without reference to the logarithms themselves *. But see †, p 76. Their use greatly facilitates many hydraulic and other engineering computations.

(*) The ratio between the mantissas of the logs of any given numbers being constant for all systems of logs, the ratio between the distances laid off on the chart or slide rule is the same for all systems, and the use of the chart or rule is independent of the system of logs used.

(2) **The logarithmic chart** consists primarily of a square,* on the sides of which the distances marked 1–2, 1–3, etc., are laid off by scale according to the logs (0.30 103, 0.47 712, etc.) of 2, 3, etc. Ordinary "squared" or **cross section paper** may of course be used for logarithmic plotting, by plotting on it the *logs* instead of their *Nos.* Lines representing Nos. may be drawn in their proper places as desired.

(3) As ordinarily constructed,‡ the **slide rule** consists essentially of four scales, A, B, C, and D, see (17), scales A and D being placed on the "rule," while B and C are placed upon the sliding piece, or "slide" As in the logarithmic chart, see (2), the scales are divided logarithmically (see figure), but *marked* with the *numbers* corresponding to the logs. Scales A and B are equal, as are also scales C and D, but a given length on A or B represents a logarithm twice as great as on C or D. See (4). Hence, each number marked on A is the *square* of the coinciding number marked on D.

(4) A single logarithmic scale is usually numbered from 1 to 10, or from 10 to 100; but it may be taken as representing any series embracing the numbers from 10^n to 10^{n+1}; as from 0.1 to 1.0 ($n = -1$); or from 1.0 to 10.0 ($n = 0$); or from 10.0 to 100.0 ($n = 1$); or—etc., etc. Here n and $n + 1$ are the **characteristics** of the corresponding logarithms.

A single scale would therefore serve for all values, from 0 to infinity; but for convenience several contiguous scales are sometimes added, as in the log chart*.

When a line reaches the limit of a square, the next square may be entered* or the same square may be re-entered at a point directly opposite. Thus, in the case of line $x^{2/3}$ ($= \sqrt[3]{x^2}$).

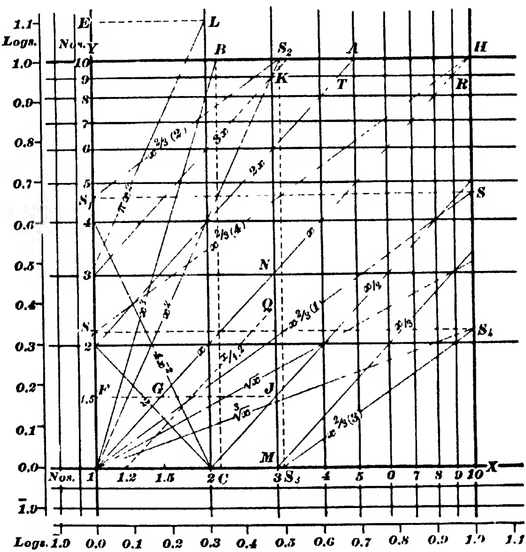
Line marked $x^{2/3}$	between	corresponds to values of	
		x from	$x^{2/3}$ from
(1)	1 and S	1 to 10	1 to 4.64
(2)	S_1 and S_2	10 to 31.62	4.64 to 10
(3)	S_3 and S_4	31.62 to 100	10 to 21.54
(4)	S_5 and H	100 to 1000	21.54 to 100

Note that the numbers, marked on any given scale, must be taken as 10 times the corresponding numbers marked in the next scale preceding, and the characteristics therefore as being greater by 1, and *vice versa*. Thus, in our figure, log 1.5 + log 2 = 1-1.5 + 1-2 = log 3 = distance 1-M. But log 15 + log 20 = (1-1 5 + 1-10) + (1-2 + 1-10), so that the characteristic of the resulting log is greater by 2, and the 3 representing the product of 15 and 20 is really in the second square to the right of that shown. In finding *roots* of numbers, remember that multiplying or dividing the *number* by 0.1, 10, 100, etc. (*i. e.*, changing the *characteristic* of its log), changes also the *mantissa* of the log of its *root*. Thus, $\sqrt[3]{2.7} = 1.39..$, (log = 0.14 379); but $\sqrt[3]{27} = 3$, (log = 0 47 712) and $\sqrt[3]{270} = 6.46..$, (log = 0.81 023). The chart or rule gives *all* such possible roots, and care must be taken to select the proper one. Most operations exceed the limits of one scale, and facility in using either instrument depends largely upon the ability to pass readily and correctly from one scale to another. This ability is best gained by practice, aided by a thorough grasp of the principles involved. Where several successive operations are to be performed, a sliding runner or marker (furnished with each slide rule) is used, in order to avoid error in shifting the slide. Detailed instructions are usually furnished with the slide rule.

(*) A common form of chart has four or more similar squares joined together. See (4). Our figure represents one complete square, with portions of adjoining squares For actual use, both charts and slide rules are, of course, much more finely subdivided than in our figures, which are given merely to illustrate the principles. Carefully engraved charts are published by Mr. John R. Freeman, Providence, R. I.

(‡) Other forms embodying the same principle are: The "Reaction Scale and General Slide Rule," by W. H. Breithaupt, M. Am. Soc. C. E.; Sexton's Omnimeter or Circular Slide Rule, by Thaddeus Norris; The Goodchild Computing Chart; The Thacher Calculating Machine or Cylindrical Slide Rule; The Cox Computers, designed for special formulas; and the Pocket Calculator, issued by "The Mechanical Engineer," London.

(5) **Multiplication and division.** For example, $2 \times 1.5 = ?$ On 1-X, in the chart, or on C or D, in the slide rule, the distance 1-1.5 represents by scale the logarithm (0.17 609) of 1.5, and 1-2 represents the logarithm (0.30 103) of 2. If now we add these two distances together, by laying off 1-2 from 1.5 on 1-X of the chart, or by placing the slide as in the figure, we obtain the distance 1-3 = .47 712 the mantissa of log 3 or of log (2×1.5).* Conversely, to divide 3 by 2, we graphically or mechanically subtract 1-2 from 1-3.



(6) **In the logarithmic chart,** the scales of both axes, 1-X and 1-Y, being equal, a line 1-H, marked x, bisecting the square and forming an angle of 45° with each axis (tan 45° = 1),† will bisect also the intersections of all *equal* co-ordinates. Thus, points in the line x, immediately over 2, 3, 4, etc., in 1-X, are also opposite 2, 3, 4, etc., respectively, on 1-Y. See (4).

(7) If lines 2-A, 3-K, etc. (marked $2x$, $3x$, etc.), parallel to *and above* 1-H, be drawn through 2, 3, etc., on 1-Y, then points in such lines, immediately over any number, x, in 1-X, will be respectively opposite the

---

(*) In the slide rule, with the slide as shown, *each* number on D is = $1.5 \times$ the coinciding number on C.

(†) In discussing tangents of angles on log chart, we refer to the actual measured distances, as shown on the equally divided scales of *logs* in our figures, and not to the *numbers*, which, for mere convenience, are *marked* on the chart. Thus, in line 1-B, $\tan C\,1\,B = \frac{C\,B}{1\,C} = \frac{1.0}{0.33}$, not $\frac{10}{2.15}$.

numbers giving the products $2x$, $3x$, etc., on 1-Y; while similar lines, drawn *below* 1-H and through 2, 3, etc, on 1-X, give values of $\frac{x}{2}$, $\frac{x}{3}$, etc., respectively If these lines $\frac{x}{2}$, $\frac{x}{3}$, etc, be produced downward, they will cut 1-Y (produced) at 0.5 (= ½), 0.33 (= ⅓), etc., respectively * See (**4**).

(**8**) **Powers and roots.** If a line x^2 be drawn through 1, at an angle S_2 1-X, whose tangent, $\frac{S_3-S_2}{1-S_3}$ is 2, it will give values of x^2. Thus, the vertical through 3, on 1-X, cuts the line x^2 opposite 9 (= 3^2) on 1-Y. Similarly, line x^3 (tangent = 3) gives values of x^3; and line $\sqrt[3]{x}$ (tangent = ⅓) gives values of $x^{\frac{1}{3}}$ or $\sqrt[3]{x}$. See (**4**).

(**9**) Any equation of the form $y = C x^n$ in which $\log y = \log C + n \log x$, (such as: area of circle = π radius²), is represented, on a logarithmic chart, by a straight line so drawn that the tangent T of its angle with 1-X is = n, and intersecting 1-Y at that point which represents the value C. Thus, the line marked πx^2, (tangent = 2) is a line of squares, and, being drawn through π (= 3.14. . .) on 1-Y, it gives values of πx^2. Thus, for a circle of radius 2, we find, in the line πx^2 over 2, a point L opposite E, or 12.57. . . , the area of such circle.† Conversely, having area = 12.57. . ., we obtain, from the diagram, radius = 2.

(**10**) If a chart is to be used for solving many equations of a single kind, such as $y = C x^n$, where C is a variable coefficient, and n a constant exponent, parallel lines, forming the proper angle with 1-X, should be permanently ruled across the sheet at short intervals.

(**11**) For any log, as 1-3 (= log 3), we may substitute its equal, M-N or 3-N, extending to the central diagonal line 1-H, marked x; and then, since, for instance, 1-1.2 = N-Q, 1-3 = N-K, etc., we may *add* any log (as 1-3) by moving *upward* from line x (as from N to K) or to the *right*, and *subtract* any log (as 1-1.2) by moving *downward* (as from N to Q) or to the *left*. This facilitates the performance of a series of operations.

Thus:

To multiply 1.5 by 2 (= 3), by 3 (= 9), and divide by 2 (= 4.5).

F-G = 1-F = log 1.5. Add G-J = 1-2 = log 2; sum = F-J = log 3 = 1-3 = M-N. Add N-K = 1-3 = log 3; sum = M-K = log 9 = 1-9 = 9-R. Subtract R-T = 1-2 = log 2; remainder = 9-T = log 4.5.

For an example of the application of this principle to engineering problems, see "Diagrams for proportioning wooden beams and posts," by Carl S. Fogh, "Engineering News", Sept. 27, 1894.

(**12**) **Negative exponents.** If x is in the *divisor*, the line will slope in the opposite direction, or downward from left to right. Thus, line 4-2 leaving 1-Y, at 4, and forming, with 1-X, the angle X, 2, 4, with tangent $= \frac{-.602 \ldots}{-.301 \ldots} = -2$, represents the equation: $y = \frac{4}{x^2} = 4\,x^{-2}$

(**13**) If the lines of products, powers, and roots, $C\,x$, x^n, and $\sqrt[n]{x}$, etc., be drawn at angles whose tangents are less by 1 than those of the angles formed by the corresponding lines in our figure, the results may be read directly from oblique lines drawn parallel to 2-2. Lines ($C\,x$) giving multiples and sub-multiples of the *first* power of x then become *horizontal* lines (tan = 0).‡

(**14**) **Powers and roots by the slide rule.** Scales C and D being twice as large as scales A and B, these scales, with their ends coinciding, form a table of squares and of square roots. See (**3**). By moving the slide we solve equations of the forms $y = (C\,x)^2$ and $y = C\,x^2$ Thus, with the

---

(*) In each of these lines, the product of the two numbers at its ends is = 10 Thus, in line 2-A. 2 × 5 = 10; in 3-K, 3 × 3.33 . . . = 10, etc. The chart thus furnishes a table of **reciprocals.**

(†) Even with full-size charts and slide rules for actual use, accuracy is not to be expected beyond the third or fourth significant figure.

(‡) A chart of this kind, prepared by Major Wm. H. Bixby, U. S. A., after the method of Léon Lalanne, Corps de Ponts et Chaussées, France, is published by Messrs. John Wiley & Sons, New York. Price, 25 cents.

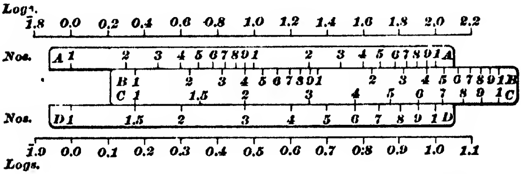
slide as shown, each number on A is = the square of (1.5 × the coinciding number on C); while, with 1 on B opposite 1.5 on A, each number on A is = 1.5 × the square of the coinciding number on C

(15) Since $x^3 = x^2 \times x$, we find cubes or third powers by placing the slide with 1 on B opposite x^2 on A (*i. e.*, opposite x on D), see (**3**), and reading x^3 from A opposite x on B. Thus, 1.5^3 = ? Place 1 on B opposite 1.5 on D; *i. e.*, opposite 1.5^2 (= 2.25) on A. Then, on A, opposite 1.5 on B, find 3.375 = 1.5^3. Or, turn the slide end for end. Place 1.5 on B opposite 1.5 on D, *i. e.*, opposite 1.5^2 = 2.25 on A. Then, adding log 1.5 (on B) to log 2.25 on A, we find 3.375 (= 1.5^3) on A opposite 1 on B.

(16) Conversely, to find $\sqrt[3]{x}$, we shift the slide (in its normal position) until we find, on B, opposite x on A, the same number as we have on D opposite 1 on C, and this number will be $\sqrt[3]{x}$. Or, turn the slide end for end,* place 1 on C opposite x on A, and find, on B, a number which coincides with its equal on D. This number is = $\sqrt[3]{x}$. See also (**17**). (**18**).

(17) On the back of the slide is usually placed a scale of logs (see scale shown below the rule in figure) and two scales of angles, marked "S" and "T" respectively, for finding sines of angles greater than 0° 34′ . . . ″, and tangents of angles between 5° 42′ . . . ″ and 45°.

(18) Placing 1 on C opposite any number x on D (with slide in its normal position), log x is read from the scale of logs by means of an index on the back of the rule. The logs may be used in finding powers and roots.



(19) To find the **sine or tangent** of an angle a; bring a, on scale S or T, as the case may be, opposite the **index** on back, and read the natural (not logarithmic) sine or tangent opposite 10 at the end of A or D: sines on B, and tangents on C. Or, invert the slide, placing S under A, and T over D, with the ends of the scales coinciding. Then the numbers on A and D are the sines and tangents, respectively, of the angles on S and T.

Caution. Sines of angles less than 5° 45′ . . . ″ are less than 0.1.
" " " " " 90° " " " 1.0.
Tangents " " betw. 5° 42′ . . . ″ and 45° are betw 0.1 and 1.0.

(20) On the back of the rule is usually printed a table of ratios of numbers in common use, for convenience in operating with the slide rule. Thus:

$\frac{\text{diameter}}{\text{circumference}} = \frac{113}{355}$; $\frac{\text{U. S. gallons}}{\text{pounds}} = \frac{3}{25}$ (in a given quantity of water).

(21) Soaping the edges of the slide and the groove in which it runs, will often cure sticking, which is apt to be very annoying. If the slide is too loose, the groove may be deepened, and small springs, cut from narrow steel tape, inserted between it and the edge of the slide.

(*) With the slide thus reversed, and with the ends of the scales coinciding, the numbers on A and B are **reciprocals** (page 52), as are also those on C and D.

LOGARITHMS OF NUMBERS TO 1000

For use of logarithms, see pp. 70, 71 and 72.

For five-place logarithms of numbers to 10,000, see pp. 80 to 91.

LOGARITHMS OF NUMBERS TO 1000. (Continued.)

For use of logarithms, see pp. 70, 71 and 72.
For five-place logarithms of numbers to 10,000, see pp. 80 to 91.

Example:
To find Log. 11826:
Log. 11830 = 07298
Dif. = 10 **36**
Log. 11820 = 07262
11826 — 11820 = **6**
Dif. for **6** under **36** = 22
Log. 11826 = 07262 + 22 = 07284

99	—361	33	49	13001	32	99	—582	31	49	—107	30	99	580	29

Example:
To find Log. 12605.
Log 12610 = 10072
Dif. = 10 **35**
Log. 12600 = 10037
12605 — 12600 = **5**
Dif. for **5** under **35** = 18
Log. 12605 = 10037 + 18 = 10055

	35	34	33	32	31	30	29	
1	4	3	3	3	3	3	3	**1**
2	7	7	7	6	6	6	6	**2**
3	11	10	10	10	9	9	9	**3**

7	25	24	23	22	22	21	20	**7**
8	28	27	26	26	25	24	23	**8**
9	32	31	30	29	28	27	26	**9**

A dash before or after a log. denotes that its true value is *less* than the tabular value by less than half a unit in the last place. Thus:
Log. 1366=1354507
" 1367=1357685

Common or Briggs Logarithms. Base = 10.

Example:
To find Log. 15414:
Log. 15420 = 18808
Dif. = 10 **28**
Log. 15410 = 18780
15414 — 15410 = **4**
Dif. for **4** under **28** = 11
Log. 15414 =
18780 + 11 = 18791

To find Log. 23335:

Log. 23340 = 36810
Dif. 20 **37**
Log. 23320 = 36773
23335 — 23320 = **15**
Under **37**
Dif. for 10 = 19
" " 5 = 9
" " **15** = 28
Log. 23335 =
36773 + 28 = 36801.

To find Log. 29019:
Log. 29020 = 46270
Dif. 20 **30**
Log. 29000 = 46240
29019 — 29000 = **19**
Under **30**
Dif. for 10 = 15
" " 9 = 14
" " **19** = 29
Log 29019 =
46240 + 29 = 46269.

A dash before or after a log. denotes that its true value is *less* than the tabular value by less than half a unit in the last place. Thus:
Log. 3128=4952667
" 3130=4955443

Common or Briggs Logarithms. Base = 10.

To find Log. 36114:
Log. 36120 = 55775
Log. 36100 = 55751
Dif. 20 **24**
36114 — 36100 = **14**
Under **24**
Dif. for 10 = 12
" " 4 = 5
" " **14** = 17
Log. 36114 =
55751 + 17 = 55768.

To find Log. 58636:
Log 58650 = 76827
Log. 58600 = 76790
Dif. 50 **37**
58636 — 58600 = **36**
Under **37**
Dif. for 10 × 3 = 22.0
" " 6 = 4.4
" " **36** = 26.4
Log. 58636 =
76790 + 26 = 76816

Common or Briggs Logarithms. Base = 10.

A dash before or after a log. denotes that its true value is *less* than the tabular value by less than half a unit in the last place. Thus:
Log.7400 = 8692317
" 7405 = 8695251

Common or Briggs Logarithms. Base = 10.

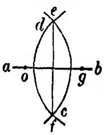
GEOMETRY.

Lines, Figures, Solids, defined. Strictly speaking a geometrical **line** is simply length, or distance. The lines we draw on paper have not only length, but breadth and thickness, still they are the most convenient symbol we can employ for denoting a geometrical line. **Straight** lines are also called **right** lines. A **vertical** line is one that points toward the center of the earth; and a **horizontal** one is at right angles to a vert one. A **plane figure** is merely any flat surface or area entirely enclosed by lines either straight or curved; which are called its outline, boundary, circumf, or periphery. We often confound the outline with the fig itself as when we speak of drawing circles, squares, &c, for we actually draw only their outlines. Geometrically speaking, a fig has length and breadth only; no thickness. **A solid** is any body; it has length, breadth, and thickness.

Geometrically similar figs or solids, are not necessarily of the same **size**; but only of precisely the same **shape**. Thus, any two squares are, scientifically speaking, similar to each other; so also any two circles, cubes, &c, no matter how different they may be in size. When they are not only of the same shape, but of the same size, they are said to be **similar**, and **equal.**

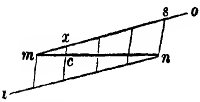
The **quantities of lines** are to each other simply as their **lengths**; but the quantities, or areas, or surfaces of similar **figures**, are as, or in proportion to, the **squares** of any one of the corresponding lines or sides which enclose the figures, or which may be drawn upon them; and the quantities, or solidities of similar **solids**, are as the **cubes** of any of the corresponding lines which form their edges, or the figures by which they are enclosed.

Rem.—Simple as the following operations appear, it is only by care, and good instruments, that they are made to give accurate results. Several of them can be much better performed by means of a metallic triangle having one perfectly accurate right angle. In the field, the tape-line, chain, or a measuring rod will take the place of the dividers and ruler used indoors.



To divide a given line, *a b*, into two equal parts.

From its ends *a* and *b* as centers, and with any rad greater than one-half of *a b*, describe the arcs *c* and *d*, and join *e f*. If the line *a b* is very long, first lay off equal dists *a o* and *b g*, each way from the ends, so as to approach conveniently near to each other, and then proceed as if *o g* were the line to be divided. Or measure *a b* by a scale, and thus ascertain its center.



To divide a given line, *m n*, into any given number of equal parts.

From *m* and *n* draw any two parallel lines *m o* and *n a*, to an indefinite dist, and on them, from *m* and *n* step off the reqd number of equal parts of any convenient length; finally, join the corresponding points thus stepped off. Or only one line, as *m o* may be drawn and stepped off, as to *s*; then join *s n*, and draw the other short lines parallel to it.

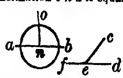
To divide a given line, *m n*, into two parts which shall have a given proportion to each other.

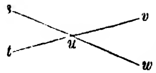
This is done on the same principle as the last; thus, let the proportion be as 1 to 3. First draw any line *m o*; and with any convenient opening of the dividers make *m x* equal to one step; and *x s* equal to three steps. Join *s n*: and parallel to it draw *x c*. Then *m c* is to *c n* as 1 is to 3.

ANGLES.

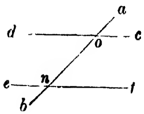
Angles. When two straight, or right lines meet each other at any inclination, the inclination is called an **angle**; and is measured by the degrees contained in the arc of a circle described from the point of meeting as a center. Since all circles, whether large or small, are supposed to be divided into 360 degrees, it follows that any number of degrees of a small circle will measure the same degree of inclination as will the same number of a large one.

When two straight lines, as *o n* and *a b*, meet in such a manner that the inclination *o n a* is equal to the inclination *o n b*, then the two lines are said to be **perpendicular** to each other; and the angles *o n a* and *o n b*, are called **right angles**; and are each measd by, or are equal to, 90°, or one-fourth part of the circumf of a circle. Any angle, as *c e d*, smaller than a right angle, is called **acute** or sharp; and one *c e f*, larger than a right angle, is called **obtuse**, or blunt. When one line meets another, as in the first Fig on opposite page, the two angles on the same side of either line are called **contiguous**, or **adjacent.** Thus, *v u s* and *s u w* are adjacent; also *t u s* and *t u w*, *s u t* and *s u v*, *w u t* and *w u v*. The sum of two adjacent angles is always equal to two right angles; or to 180°. Therefore, if we know the number of degrees contained in one of them, and subtract it from 180°, we obtain the other



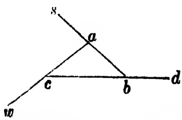


When two straight lines *cross* each other, forming four angles, either pair of those angles which point in exactly opposite directions are called **opposite**, or **vertical angles**: thus, the pair *s u t* and *v u w* are opposite angles; also the pair *s u v* and *t u w*. The opposite angles of any pair are always equal to each other.



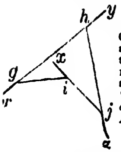
When a straight line *a b* crosses two parallel lines *c d*, *e f*, the **alternate** angles which form a kind of Z are equal to each other. Thus, the angles *d o n* and *o n f* are equal as are also *c o n* and *o n e*. Also the sum of the two internal angles on the same side of *a b*, is equal to two right angles, or 180°; thus, *c o n* + *o n f* = 180°; also *d o n* + *o n e* = 180°.

An interior angle,



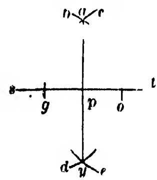
In any fig. is any angle formed *inside* of that fig, by the meeting of two of its sides, as the angles *c a b*, *a b c*, *b c a*, of this triangle All the interior angles of any straight-lined figure of any number of sides whatever, are together equal to twice as many right angles minus four, as the figure has sides Thus, a triangle has 3 sides, twice that number is 6; and 6 right angles, or 6 × 90° = 540°, from which take 4 right angles, or 360°; and there remain 180°, which is the number of degrees in every plane, or straight lined triangle. This principle furnishes an easy means of testing our measurements of the angles of any fig. for if the sum of all our measurements does not agree with the sum given by the rule, it is a proof that we have committed some error.

An exterior angle



Of any straight-lined figure, is any angle, as *a b d*, formed by the meeting of any side, as *a b*, with the prolongation of an adjacent side, as *c b*; so likewise the angles *c a s* and *b c w*. All the exterior angles of any straight-lined fig, no matter how many sides it may have, amount to 360°; but, in the case of a *re-entering* angle, as *g i j*, the interior angle, *g i j*, exceeds 180°, and the "exterior" angle, *g i x*, being = 180° − interior angle, is *negative*. Thus *a b d* + *b c w* + *c a s* = 360°; and *y h j* + *z j i* − *g i x* + *i g w* = 360°. Angles, as *a*, *b*, *c*, *g*, *h*, and *j*, which point *outward*, are called **salient.**

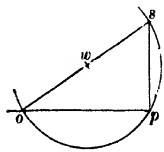
From any given point, *p*, on a line *s t*, to draw a perp, *p a*.



From *p*, with any convenient opening of the dividers, step off the equals *p o*, *p g* From *o* and *g* as centers, with any opening greater than half *o g*, describe the two short arcs *b* and *c*; and join *a p*. Or still better, describe four arcs, and join *a y*.

Or from *p* with any convenient scale describe two short arcs through *g* and *a*, either one of them with a radius 3, and the other with a rad 4. Then from *g* with rad 5 describe the arc *b*. Join *p a*

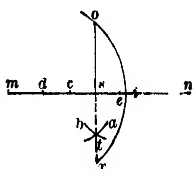
If the point *p* is at one end of the line, or very near it,



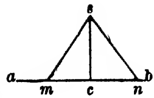
Extend the line, if possible, and proceed as above. But if this cannot be done, then from any convenient point, *w*, open the dividers to *p*, and describe the semicircle, *s p o*, through *o w* draw *o w s*, join *p s*.

Or use the last foregoing process with rads 3, 4, and 5.

From a given point, *o*, to let fall a perp *o s*, to a given line, *m n*.

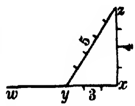


From *o*, measure to the line *m n*, any two equal dists, *o c*, *o e*; and from *c* and *e* as centers, with any opening greater than half of *c e*, describe the two arcs *a* and *b*; join *o t*. Or from any point, as *d* on the line, open the dividers to *o*, and describe the arc *o g*; make *i x* equal to *i o*; and join *o x*.



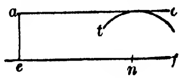
If the line, *a b*, is on the ground,

And a perp is reqd to be drawn from *c*, first measure off any two equal dists, *c m*, *c n*. At *m* and *n*, hold the ends of a piece of string, tape line, or chain, *m s n*; then tighten out the string, &c, as shown by *m s n*; *s* being its center. Then will *s c* be the reqd perp. Or if the perp *x z* is to be drawn from the *end* of the line *w x*, first measure *x y* upon the line, and equal to three feet, then holding the end of a tape-line at *x*, and its nine feet mark at *y*, hold the four feet mark at *z*, keeping *x z* and *z y* equally stretched. Then *x z* will be the reqd perp, because 3, 4, and 5, make the sides of a right-angled triangle Instead of 3, 4, and 5, any multiples of those numbers may be used, such as 6, 8, and 10; or 9, 12, 15, &c: also instead of feet, we may use yards, chains, &c.



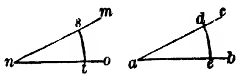
Through a given point, *a*, to draw a line, *a c*, parallel to another line, *e f*.

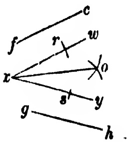
With the perp dist, *a e*, from any point, *n*, in *e f*, describe an arc, *t*; draw *a c* just touching the arc.



At any point, *a*, in a line *a b*, to make an angle *c a b*, equal to a given angle, *m n o*.

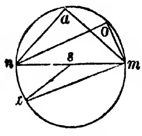
From *n* and *a*, with any convenient rad, describe the arcs *s t*, *d e*; measure *s t*, and make *e d* equal to it; through *a d* draw *a c*.



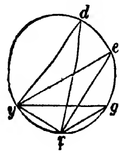


To bisect, or divide any angle, *w x y*, into two equal parts.

From *x* set off any two equal dists, *x r*, *x s*. From *r* and *s* with any rad describe two arcs intersecting, as at *o*; and join *o x*. If the two sides of the angle do not meet, as *c f* and *g h*, either first extend them until they do meet; or else draw lines *x w*, and *x y*, parallel to them, and at equal dists from them, so as to meet; then proceed as before.



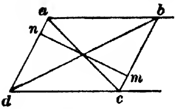
All angles, as *n a m*, *n o m*, at the circumf of a semicircle, and standing on its diam *n m*, are right angles; or, as it is usually expressed, **all angles in a semicircle are right angles.** An angle *n s x* at the center of a circle, is twice as great as an angle *n m x* at the circumf, when both stand upon the same arc *n x*.



All angles, as *y d p*, *y e p*, *y g p*, at the circumf of a circle, and standing upon the same arc, as *y p*, are equal to each other; or, as usually expressed, **all angles in the same segment of a circle are equal.**

The **complement** of an angle is what it lacks of 90°. Thus, the complement of 80° is 90° — 80° = 10°; and that of 210° is 90° — 210° = — 120°. The **supplement** of an angle is what it lacks of 180°. Thus, the supplement of 80° is 180° — 80° = 100°; and that of 210° is 180° — 210° = — 30°. But ordinarily we may neglect the signs + and —, before complements and supplements, and call the complement of an angle its *diff* from 90°; and the supplement its *diff* from 180°.

Angles in a Parallelogram.



A parallelogram is any four-sided straight-lined figure whose opposite sides are equal, as *a b c d*; or a square, &c. Any line drawn across a parallelogram between 2 opposite angles, is called a *diagonal*, as *a c*, or *b d*. A diag divides a parallelogram into two equal parts; as does also any line *m n* drawn through the center of either diag; and moreover, the line *m n* itself is div into two equal parts by the diag. Two diags bisect each other; they also divide the parallelogram into four triangles of equal areas. The sum of the two angles at the ends of any one side is = 180°; thus, *d a b* + *a b c* = *a b c* + *b c d* = 180°, and the sum of the four angles, *d a b, a b c, b c d, c d a* = 360°.

The sum of the squares of the four sides is equal to the sum of the squares of the two diags.

To reduce Minutes and Seconds to Degrees and decimals of a Degree, etc.

In any given angle—

Number of degrees = Number of minutes ÷ 60.
= Number of seconds ÷ 3600.

Number of minutes = Number of degrees × 60.
= Number of seconds ÷ 60.

Number of seconds = Number of degrees × 3600.
= Number of minutes × 60.

Table of Minutes and Seconds in Decimals of a Degree, and of Seconds in Decimals of a Minute.

(The* columns of Mins and Degs answer equally for Secs and Mins.)

Mins.	Deg.	Mins.	Deg.	Mins.	Deg.	Secs.	Deg.	Secs.	Deg.	Secs.	Deg.
In each equivalent, **the last digit repeats indefinitely.** See * below

* Each equivalent is a **repeating decimal,** thus:

2 minutes = 0.0333333 . . . . degree
7 " = 0.1166666 . . . "
12 " = 0.2000000 . . . . "

12 seconds = 0.2000000 . . . . minute
1 second = 0.0002777 . . . . degree
50 seconds = 0.0138888 . . . . "

Approximate Measurement of Angles.

(1) **The four fingers of the hand,** held at right angles to the arm and at arm's length from the eye, cover about 7 degrees And an angle of 7° corresponds to about 12.2 feet in 100 feet; or to 36 6 feet in 100 yards; or to 645 feet in a mile.

(2) **By means of a two-foot rule,** either on a drawing or between distant objects in the field. If the inner edges of a common two-foot rule be opened to the extent shown in the column of inches, they will be inclined to each other at the angles shown in the column of angles Since an opening of ⅛ inch (up to 19 inches or about 105°) corresponds to from about ½° to 1°, no great accuracy is to be expected, and beyond 105° still less, for the liability to error then increases very rapidly as the opening becomes greater Thus, the last ⅛ inch corresponds to about 12°.

Angles for openings intermediate of those given may be calculated to the nearest minute or two, by simple proportion, up to 23 inches of opening, or about 147°.

Table of Angles corresponding to openings of a 2-foot rule.

(3) **With the same table, using feet instead of inches.** From the given point measure 12 *feet* toward * each object, and place marks. Measure the distance in *feet* between these marks. Suppose the first column in the table to be *feet* instead of inches. Then opposite the distance in *feet* will be the angle.

⅛ foot = 1.5 inches.

1 in. = .083 ft.	4 ins. = .333 ft.	7 ins. = .583 ft.	10 ins = .833 ft.
2 ins. = .167 ft.	5 ins. = .416 ft.	8 ins. = .667 ft.	11 ins = .917 ft.
3 ins. = .25 ft.	6 ins. = .5 ft.	9 ins. = .75 ft.	12 ins. = 1 0 ft.

(4) **Or, measure toward * each object** 100 or any other number of feet, and place marks. Measure the distance in feet between the marks. Then

$$\text{Sine of } \textit{half} \text{ the angle} = \frac{\textit{half} \text{ the distance between the marks}}{\text{the distance measured toward one of the objects}}.$$

Find this sine in the table pp. 98, etc.; take out the corresponding angle and multiply it by 2

(5) **See** last paragraph of foot-note, pp 152 and 153.

* If it is inconvenient to measure *toward* the objects, measure directly *from* them.

PLANE TRIGONOMETRY.

For illustrations, see p 97 *d*.

1. Usual measure of angles. If a circle be divided into 360 equal arcs, each of these arcs, or the angle at center, subtended by it, is called a **degree** (°). Each degree is subdivided into 60 **minutes** (′) and each minute into 60 **seconds** (″). **A right angle** is an angle of 90°.

2. Circular measure of angles. The arc whose length is equal to the radius, or the angle at center subtended by such arc, is called a **radian.** Since the semi-circumf (see p 161) is = π × radius = π radians = 180°, we have

$$\textbf{1 radian} = \frac{180^\circ}{\pi} = \frac{180^\circ}{3.14159+} = 57.2957795\ldots^\circ. \quad \text{Log} = 1.758\ 1226.$$

$$\left.\begin{array}{l} 1 \text{ degree} = 0.017\ 453\ 292\ 520 \text{ radian;} \\ 1 \text{ minute} = 0.000\ 290\ 888\ 209 \text{ radian;} \\ 1 \text{ second} = 0.000\ 004\ 848\ 137 \text{ radian;} \end{array}\right\} \text{see table, p 185.}$$

3. Ratio of arc to radius. In any angle, the length of the arc, in terms of the radius, may be called **the arc** of the angle. Thus, in Figs **1*** and 3*, arc $A = ZB \,/\, OZ$. For other angular ratios, see ¶¶ 6 and 10.

4. Positive and negative angles. In Fig 1*, suppose a radius, as OZ, to sweep around the whole or part of the circle to the *left* or *counter-clockwise*, as indicated by the arrow. Angles or arcs, as ZB, BC, ZBC, CDE, $ZBCDE$, *thus* described, are considered **positive,** e g, arc $ZBCDE$ = +280°; while angles described by a radius travelling in the *opposite* or *clockwise* direction, as ZE, EDC, $ZEDCB$, are considered **negative,** e g, arc ZE = −80°.

5. Complement, Supplement, etc. For any angle, A, we have:
complement $A = 90° - A$; **supplement** $A = 180° - A$;
explement $A = 360° - A$. See ¶ 7.

6. Angular functions, or **angular ratios,** are the ratios between the sides of a right-triangle, Fig 2*. The principal ratios of an angle, A, are the **sine** (sin A), **cosine** (cos A), **tangent†** (tan A), **cosecant** (csc A,) **secant** (sec A), and **cotangent** (cot A or ctn A). For other ratios, see ¶¶ 3 and 10.

In Fig 2*

$$\textbf{Sin A} = \frac{a}{c} = \frac{\text{opposite side}}{\text{hypotenuse}}; \quad \textbf{csc A} = \frac{1}{\sin A} = \frac{c}{a} = \frac{\text{hypotenuse}}{\text{opposite side}};$$

$$\textbf{Cos A} = \frac{b}{c} = \frac{\text{adjacent side}}{\text{hypotenuse}}; \quad \textbf{sec A} = \frac{1}{\cos A} = \frac{c}{b} = \frac{\text{hypotenuse}}{\text{adjacent side}};$$

$$\textbf{Tan A} = \frac{a}{b} = \frac{\text{opposite side}}{\text{adjacent side}}; \quad \textbf{cot A} = \frac{1}{\tan A} = \frac{b}{a} = \frac{\text{adjacent side}}{\text{opposite side}}$$

7. If we represent the denominator, in each of the ratios of ¶ 6, by a line of unit length, then the **length of the line** representing the numerator gives the value of the ratio. Thus, in Fig 3*, let radius OB = 1, angle ZOU = 90°, ZOB = any angle, A, and let MB and ZB' be perpendicular to OZ. Then:

$$\textbf{sin A} = MB; \quad \textbf{cos A} = OM = U'B; \quad \textbf{tan A} = ZB';$$
$$\textbf{csc A} = OB''; \quad \textbf{sec A} = OB'; \quad \textbf{cot A} = UB''.$$

The sine (etc), thus expressed, was formerly called the **natural sine** (etc), or sine (etc) **to radius 1.**

Note that

$$\begin{array}{l} \cos A = \sin(90^\circ - A) = \sin(\text{complement } A) \\ \cot A = \tan(90^\circ - A) = \tan(\text{complement } A) \\ \csc A = \sec(90^\circ - A) = \sec(\text{complement } A). \end{array}$$

See ¶ 13.

---

* **For illustrations,** see p 97 *d*.

† This use of the word "tangent" was suggested by its use in geometry where it denotes any line touching a curve without intersecting it. In the location of railroad curves, the name "tangent" is often given to the "apex distance," which is the trigonometrical tangent of half the curve.

8. Positive and negative signs. Fig 4*. Suppose the circle divided into four quadrants, I, II, III and IV, beginning on the right of and above the center, and progressing to the left, or counter-clockwise. Then, vertical or horizontal lines, measured upward from, or to the right of, the horizontal and vertical diameters, respectively, are considered positive; while such lines measured downward from, or to the left of, the same diams, are considered negative; but the radius, in whatever quadrant it may lie, is always considered pos when measured from the center outward. Hence,

For equations between angular functions, see ¶¶ 14 to 19.

10. Other Functions. See also ¶¶ 3 and 6.

In Fig 3*, BN = chord 2 A = 2 sin A ; and **chord A** = 2 sin (A/2).*

The versed sine, MZ, Fig 3, of an angle, A, is vers A = 1 — cos A. It is much used in connection with the location of railroad curves.

The coversed sine (covers), $U'U$, = 1 — sin A, Fig 3, of an angle, A, is the versed sine of the complement, BOU, of A.

By their definitions, vers A (= 1 — cos A) and covers A (= 1 — sin A) are always pos. In the 4 quadrants, Fig 4*, their values change as follows:

Quadrant	**I**	**II**	**III**	**IV**
Including angles from	0° to 90°	90° to 180°	180° to 270°	270° to 360°
Versed sine	0 to 1	1 to 2	2 to 1	1 to 0
Coversed sine	1 to 0	0 to 1	1 to 2	2 to 1

The external secant (exsec) $B B'$, Fig 3, of an angle, A, = sec A — 1. Like the versed sine, it is used in the location of railroad curves.

* **For illustrations**, see p 97 *d*.

Table of sines, tans, cotans, cosines.

For logarithmic sines, etc., see pp 143 *a*, etc.

11. Table of Natural Angular Ratios. The table, pp 98–142, contains the natural sines, tangents, cotangents and cosines of angles from 0° to 90°, progressing by single minutes. Functions for intermediate angles can be found, in nearly all cases, with sufficient approximation, by simple proportion. **For functions not given in the table,** we have:

Secant $A = 1/\cos A$; Versed sine $A = 1 - \cos A$;
Cosecant $A = 1/\sin A$; Coversed sine $A = 1 - \sin A$;
Chord $A = 2 \sin (A/2)$; External secant $A = \sec A - 1 = (1/\cos A) - 1$.

12. Angle as function of ratio. The arc (or angle) whose sin, tan, etc, is f, is called, by continental writers, arc sin f, arc tan f, etc, or anti-sin f, anti-tan f, etc, and, by English writers, $\sin^{-1} f$, $\tan^{-1} f$, etc.

Thus, let A = the angle; $f' = \sin A$; $f'' = \cos A$. Then

$$A = \text{arc}\sin f' = \text{anti-sin} f' = \sin^{-1} f'$$
$$= \text{arc}\cos f'' = \text{anti-cos} f'' = \cos^{-1} f''.$$

Example. Let $A = 30°$ Then $f' = \sin 30° = 0.5$; $f'' = \cos 30° = 0.866\ldots$, and

$$30° = \text{arc}\sin 0.5 = \text{anti-sin}\ 0.5 = \sin^{-1} 0.5$$
$$= \text{arc}\cos 0.866\ldots = \text{anti-cos}\ 0.866\ldots = \cos^{-1} 0.866\ldots$$

Functions of Supplements and Complements.

13. Putting A = any angle, and F = "any trig function of," we have the following convenient rules, see Fig 5: (For vers and covers, see p 97*a*, ¶ 10.)

$F\,[\pm A \pm$ (an *even* multiple of 90°)] numerically = *same* function of A;
$F\,[\pm A \pm$ (an *odd* multiple of 90°)] numerically = *co-named* function of A;
the sign being determined, in each case, by considering the quadrants in which the angles lie. (See ¶ 8.) Thus, numerically.

$$\begin{aligned}
\sin A &= \sin (180° + A) = \sin (180° - A) = \sin (A - 180°) \\
&= \cos (\ 90° + A) = \cos (\ 90° - A) = \cos (A - \ 90°); \\
\cos A &= \cos (180° + A) = \cos (180° - A) = \cos (A - 180°) \\
&= \sin (\ 90° + A) = \sin (\ 90° - A) = \sin (A - \ 90°); \\
\tan A &= \tan (180° + A) = \tan (180° - A) = \tan (A - 180°) \\
&= \cot (\ 90° + A) = \cot (\ 90° - A) = \cot (A - \ 90°).
\end{aligned}$$

Properties of the trigonometric functions, Figs 6, 7, 8.

14. For any angle, A, we have:

$$\tan A = \frac{\sin A}{\cos A}; \qquad \sin^2 A + \cos^2 A = 1;$$

$$1 + \tan^2 A = \sec^2 A; \qquad 1 + \cot^2 A = \csc^2 A;$$

$$\cot A = \frac{1}{\tan A} = \frac{\cos A}{\sin A}; \quad \sec A = \frac{1}{\cos A}; \quad \csc A = \frac{1}{\sin A} = \frac{\sec A}{\tan A}.$$

From Fig 4, $\sin(-A) = -\sin A$; $\tan(-A) = -\tan A$; and $\cos(-A) = \cos A$.

15. For any two angles, A and B, it may be shown that

$$\sin (A + B) = \sin A \,.\, \cos B + \cos A \,.\, \sin B;$$
$$\text{and } \cos (A + B) = \cos A \,.\, \cos B - \sin A \,.\, \sin B;$$

whence, dividing by $\dfrac{\cos A \ \cos B}{\cos A \,.\, \cos B}$, we obtain

$$\tan (A + B) = \frac{\sin (A + B)}{\cos (A + B)} = \frac{\tan A + \tan P}{1 - \tan A \tan B}.$$

16. Putting $A = B$, in the formulas for $(A + B)$, we have

$$\mathbf{\sin 2A} = 2 \sin A \,.\, \cos A;$$
$$\mathbf{\cos 2A} = \cos^2 A - \sin^2 A = 1 - 2 \sin^2 A = 2 \cos^2 A - 1;$$
$$\mathbf{\tan 2A} = \frac{2 \tan A}{1 - \tan^2 A}.$$

and, changing B to $-B$, we have

$$\mathbf{\sin (A - B)} = \sin A \,.\, \cos B - \cos A \,.\, \sin B;$$
$$\mathbf{\cos (A - B)} = \cos A \,.\, \cos B + \sin A \,.\, \sin B;$$
$$\mathbf{\tan (A - B)} = \frac{\tan A - \tan B}{1 + \tan A \,.\, \tan B}.$$

17. Since $\cos 2A = 1 - 2\sin^2 A$, we have: (putting $A/2$ for A) $\cos A = 1 - 2\sin^2\frac{A}{2}$; or $\sin\frac{A}{2} = \sqrt{\frac{1-\cos A}{2}}$; and, since $\cos 2A = 2\cos^2 A - 1$, we have $2\cos^2\frac{A}{2} = \cos A + 1$, or $\cos\frac{A}{2} = \sqrt{\frac{1+\cos A}{2}}$

and hence $\tan\frac{A}{2} = \frac{\sin A/2}{\cos A/2} = \sqrt{\frac{1-\cos A}{1+\cos A}} = \frac{1-\cos A}{\sin A} = \frac{\sin A}{1+\cos A}$.

18. Formulas transforming a sum or difference into a product. Combining the formulas for $\sin(A \pm B)$ and $\cos(A \pm B)$, we have, finally:

$$\sin A + \sin B = 2\sin\frac{A+B}{2}\cdot\cos\frac{A-B}{2}$$

$$\sin A - \sin B = 2\sin\frac{A-B}{2}\cdot\cos\frac{A+B}{2}$$

$$\cos A + \cos B = 2\cos\frac{A+B}{2}\cdot\cos\frac{A-B}{2}$$

$$\cos A - \cos B = -2\sin\frac{A+B}{2}\cdot\sin\frac{A-B}{2}$$

See also ¶ 20, for formulas used in solution of triangles.

19. Any function of an angle may be expressed **in terms of any other.** Thus, Figs 6, 7, 8:

in terms of the **sine:**

$$\cos^2 A = 1 - \sin^2 A; \quad \text{hence, } \cos A = \sqrt{1 - \sin^2 A};$$

$$\tan A = \frac{\sin A}{\cos A} = \frac{\sin A}{\sqrt{1-\sin^2 A}};$$

$$\sec A = \frac{1}{\cos A} = \frac{1}{\sqrt{1-\sin^2 A}};$$

in terms of the **tangent:**

$$\sec^2 A = 1 + \tan^2 A; \quad \text{hence, } \sec A = \sqrt{1+\tan^2 A};$$

$$\cos A = \frac{1}{\sec A} = \frac{1}{\sqrt{1+\tan^2 A}};$$

$$\sin A = \frac{\tan A}{\sec A} = \frac{\tan A}{\sqrt{1+\tan^2 A}}.$$

20. Formulas used in the solution of triangles. Fig 9. Let a, b, c be the sides of any plane triangle, and A, B, C the angles opposite a, b, c respectively. Then

$$\frac{\sin A}{\sin B} = \frac{a}{b};$$

See also pp 148 to 156.
See Case 2, p 150.

$$a^2 = b^2 + c^2 - 2bc\cos A;$$

$$\tan\frac{A-B}{2} = \frac{a-b}{a+b}\cdot\tan\frac{A+B}{2};$$

$$\tan\frac{A}{2} = \frac{r}{s-a}; \text{ where } s = \frac{a+b+c}{2};$$

$$\text{and } r = \sqrt{\frac{(s-a)(s-b)(s-c)}{s}}$$

= radius of inscribed circle.

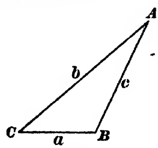

Fig. 9.

$$\text{Area of the triangle} = \frac{ab\sin C}{2} = rs = \sqrt{s(s-a)(s-b)(s-c)}$$

$$= \frac{\sin A \sin C\, b^2}{2\sin B}.$$

Tables of

Logarithmic Sines, Cosines, Tangents
and Cotangents,

with Introduction.

(55 pages in all.)

LOGARITHMIC TRIGONOMETRIC FUNCTIONS.

(Logarithms of trigonometric ratios.)

(1) **The "logarithmic" sine, tangent, etc.** (log sin, log tan, etc.), of an arc is the *logarithm* of the *natural* sin, tang, etc., of the arc. Thus:

$$\begin{aligned} \text{nat sin } 37^\circ &= 0.60182; \text{ and} \\ \text{log sin } 37^\circ &= \text{log } 0.60182 = \bar{1}.779\,463 \\ &= 0.779\,463 - 1 \\ &= 9.779\,463 - 10. \end{aligned}$$

In tables, in order to avoid negatives, the *third* form (log sin 37° = 9 779 463 — 10) is used; but the " — 10" is omitted, because understood.

*TWO TABLES.

We give **two tables** of logarithmic trigonometric functions, viz: a **"main table,"** pp 143 *l* to 146 *b*

and a

"special table," pp 143 *c* to 143 *k*.

The main table gives these functions **for each minute of the quadrant** from 0° to 90°.

The special table gives them **at smaller intervals, for small and large angles** (from 0° to 2°, and from 88° to 90°), in which certain functions change so rapidly that one-minute intervals, between arcs, give values of the functions differing too widely for satisfactory interpolation. See ¶¶ 7 to 9.

Main Table.

(2) **The main table,** pp. 143 *l* to 146 *b*, gives, to 6 decimal places, the **log sin, log cos, log tan and log cot**†

of the arc for each minute of the quadrant, or from 0° 0′ to 89° 60′ (90°). See also (6), below.

(3) For arcs from 0° to 45°, **read downward,** as in the left-hand column of minutes, using the titles at the *heads* of the columns. For arcs from 45° to 90°, **read upward,** as in the right-hand column, using the titles at the *feet* of the columns.

(4) **Example,** to find log sin 7° 34′. At head of page [143s] on the left, in bold type, we find 7°; and, under it, in the first column, or column of minutes (reading *downward*), we find 34; opposite which, in the next or 2d column, *under* "Sine," we find 9.119 519, the reqd log sin of 7° 34′.

(5) **Example,** to find log cos 82° 26′. At foot of page [143s], on the right, in bold type, we find 82°; and, over this, in the right-hand column, or column of minutes (reading *upward*), we find 26; opposite which, in the second column from the left, *over* "Cosine," we find 9.119 519, the required log cos 82° 26′.

(6) **For arcs between 90° and 180°,** we have the relations:

$$\sin a = \sin (180^\circ - a); \qquad \cos a = 0 - \cos (180^\circ - a);$$
$$\tan a = 0 - \tan (180^\circ - a); \qquad \cot a = 0 - \cot (180^\circ - a).$$

Hence, log sin, log cos, log tan and log cot of an angle, a, between 90° and 180°, are numerically the same as log sin, log cos, log tan and log cot, respectively, of the **supplementary angle,** 180° — a. In the main table, these functions may be found directly from the table, by using the headings, in bold type, in the lower left-hand and upper right-hand corners of the pages.

For degs on left or r't (resp) of page, use left or r't hand (resp) min col.
For degs at top or ft (resp) of page, use headgs at top or ft (resp) of page.

Thus: log sin 172° 26′ = 9.119 519;
log cos 172° 26′ = 9.996 202.

---

* Reproduced, by permission of author and publishers, from "Field Engineering," by Wm. H. Searles, pubd by John Wiley & Sons, New York.

† **Secant** $a = \frac{1}{\cos a}$; log sec a = 0 — log cos a. **Cosecant** $a = \frac{1}{\sin a}$; log cosecant a = 0 — log sin a.

(7) For arcs intermediate of those given in the main table (pp 143 *l* to 146 *b*); if the arc is not between 0° and 2°, or between 88° and 92°, or between 178° and 180° (see ¶¶ 8 and 9), **interpolate,** by means of the column headed D.1" (difference of function for 1 second of angle), as in the following examples:

Given	Required	Table gives D.1" = 15.87, and 9.118 567 =	Result.
a = 7° 33′ 12″	log sin a	log sin 7° 33′ 0″	9.118 567 + 12 D. 1″ = 9.118 757;
a = 82° 26′ 48″	log cos a	log cos 82° 27′ 0″	9.118 567 + 12 D. 1″ = 9.118 757;
log sin a = 9.118 757	a	log sin 7° 33′ 0″	7° 33′ 0″ + $\frac{190^*}{\text{D. 1}''}$ = 7° 33′ 12″;
log cos a = 9.118 757	a	log cos 82° 27′ 0″	82° 27′ 0″ − $\frac{190^*}{\text{D. 1}''}$ = 82° 26′ 48″

Special Table, pp. 143 *c* to 143 *k*.

(8) For the log sin, tan, cot, of arcs from 0° 0′ to 1° 60′ (2° 0′); and for the log cos, cot, tan, of arcs from 88° 0′ to 89° 60′ (90° 0′); the differences, between successive logs, vary so rapidly that the use of the column D. 1″, with intervals of 1 minute between tabular arcs, would give insufficiently accurate results.

(9) For such cases we give the **special 5-place table,** pp. 143 *c* to 143 *k*, with smaller intervals between arcs, viz:

for arcs from	interval	pages
0° 0′ to 0° 18′	1 second	143 *c* – *e*
0° 18′ to 0° 30′	3 seconds	143 *f* – *g*
0° 30′ to 0° 40′	5 "	143 *h*
0° 40′ to 0° 60′	10 "	143 *j*
1° 0′ to 1° 60′	30 "	143 *k*

(10) Tangents of angles near 90°, and cotangents of angles near 0°, are not given in the special table; but we have:

log tan a = 0 − log cot a; log cot a = 0 − log tan a.

(11) With functions to only five decimal places, we have:

in arcs from 0° to 0° 18′; log sin a = log tan a = 0 − log cot a;
" " " 89° 42′ to 90°; log cos a = log cot a = 0 − log tan a.

(12) For arcs from 0° 0′ to 0° 18′ (1 second intervals) of course no interpolation is required for whole seconds. For the other angles, named above, the greatest **error, due to interpolation,** is less than 1 in the 5th place. In the main table, log sin 2° 0′ 30″, the error, due to interpolation, is nearly 0.4 in the 5th place.

Examples of interpolation in use of special table.

	Table gives	
Given, a = 1° 48′ 10″	log sin 1° 48′ 30″ =	8.49 908
Required, log sin a	log sin 1° 48′ 0″ =	8.49 708
	diffs 0° 0′ 30″	0.00 200

Result = log sin a = 8.49 708 + $\frac{10}{30}$ × 200 = 8.49 775.

	Table gives	
Given, log sin a = 8.49 775	8.49 908 =	log sin 1° 48′ 30″
Required, a	8.49 708 =	log sin 1° 48′ 0″
	diffs 0.00 200	0° 0′ 30″

Result = a = 1° 48′ 0″ + $\frac{67\dagger}{200}$ × 30″ = 1° 48′ 10″.

* 9.118 757 − 9.118 567 = 0.000 190.

† 67 = 8.49 775 − 8.49 708.

Log sine = Log tangent = 0 − Log cotangent.

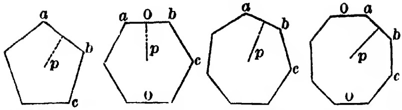
POLYGONS.



Pentagon. 5 *sides*. **Hexagon.** 6 *sides*. **Heptagon.** 7 *sides*. **Octagon.** 8 *sides*.

Any straight-sided fig is called a polygon. If all the sides and angles are equal, it is a **regular** polygon; if not, it is **irregular**. Of course the number of polygons is infinite.

Table of Regular Polygons.

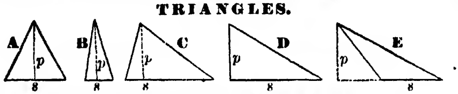
Number of Sides.	Name of Polygon.	**Area** = (square of one side) mult by	**Radius** of circumscribing circle = side mult by	**Interior angle** *a b c* contained between two sides.	**Angle at cen.** subtended by a side.
3	Equilateral triangle.	.433013	.577350	60°	120°
4	Square.	1.000000	.707107	90°	90°
5	Pentagon.	1.720477	.850651	108°	72°
6	Hexagon.	2.598076	1.000000	120°	60°
7	Heptagon.	3.633912	1.152382	128° 34 2857′	51° 25.7143
8	Octagon.	4 828427	1.306563	135°	45°
9	Nonagon.	6 181824	1 461902	140°	40°
10	Decagon.	7.694209	1.618034	144°	36°
11	Undecagon.	9 365640	1.774733	147° 16.3636′	32° 43.6364′
12	Dodecagon	11.196152	1.931854	150°	30°

Area of any regular polygon = length of one side, *a b* × perp *p* drawn from cen of fig to cen of side × half the number of sides.

Sum of interior angles, a b c, etc, **of any polygon, regular or irregular** = 180° × (number of sides — 2)

Angle at cen subtended by a side, in any regular polygon = 360° ÷ number of sides

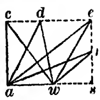
TRIANGLES.



We speak here of **plane** triangles only; or those having **straight** sides.

A triangle is equilateral when all its sides are equal, as A, **isosceles** when only two sides are equal, as B, **scalene** when all the sides are unequal, as C, D and E **acute-angled** when all its angles are acute, or each less than 90°, as A, B, and C, **right-angled** when it contains a right angle, as D **obtuse-angled** when it contains an obtuse angle, or one greater than 90°, as E

All the three angles of any triangle are equal to two right angles, or 180°, therefore, if we know two of them, we can find the third by subtracting their sum from 180°. **All triangles which have equal bases,** and equal perp heights, have also equal areas, thus the areas of *a w c*, *a u d*, and *a w e*, are equal to each other. **The area of any triangle** is equal to half that of any parallelogram which has an equal base, and an equal perp height. **The areas of triangles which have equal bases,** but diff perp heights, are to each other as, or in proportion to, their perp heights, thus the triangle *a w n*, with a perp height *s n*, equal to but one-half that (*s e*) of the three other triangles, but with the same base *a w*, has also but half the area of either of those others.



Area of any triangle, Figs A, B, C, D, E, = half the base, S, × the height, or perp dist *p* to the opposite angle Any side may be taken as the base of a triangle; but the perp height must always be measured from the side so assumed; to do which, the side must sometimes be prolonged, as in Fig E, but the prolongation is not to be considered as a part of the base

Area of any equilateral triangle = .433013 × square of one side.

To find area, having the three sides.

Add them together; div the sum by 2; from the half sum, subtract each side separately; mult the half sum and the three remainders continuously together; take the sq rt of the prod.

Ex.—The three sides = 20, 30, 40 ft. Here $20 + 30 + 40 = 90$; and $\frac{90}{2} = 45$. And $45 - 20 = 25$ $45 - 30 = 15$; and $45 - 40 = 5$. And $45 \times 25 \times 15 \times 5 = 84375$· and the sq rt of 84875 is 290.47 sq ft area reqd.

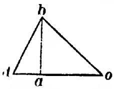
To find area, having one side and the 2 angles at its ends.

Add the 2 angles together; take the sum from 180°, the rem will be the angle opp the given side. Find the nat sine of this angle; also find the nat sines of the other angles, and mult them together. Then as the nat sine of the single angle, is to the prod of the nat sines of the other 2 angles, so is the *square* of the given side to *double* the reqd area.

To find area, having two sides, and the included angle.

Mult together the two sides, and the nat sine of the included angle; div by 2.

Ex —Sides 650 ft and 980 ft, included angle 69° 20'. By the table we find the nat sine .9356; therefore, $\frac{650 \times 980 \times .9356}{2} = 297988.6$ square ft area.



To find area, having the three angles and the perp height, *a b*.

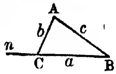
Find the nat sines of the three angles; mult together the sines of the angles *d* and *o*; div the sine of the angle *b* by the prod; mult the quot by the square of the perp height *a b*; div by 2.

To find any side, as *d o*, having the three angles, *d*, *b* and *o*, and the area.

(Sine of *d* × sine of *o*) : sine of *b* :: **twice** the area : **square** of *d o*.

The perp height of an equilateral triangle is equal to one side × .866025 Hence one of its sides is equal to the perp height div by .866025 or to perp height × 1.1547. Or, **to find a side**, mult the sq rt of its area by 1.51967. The side of an equilateral triangle, mult by .658037 = side of a square of the same area; or mult by .742517 it gives the diam of a circle of the same area.

The following apply to any plane triangle, whether oblique or right-angled:



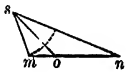
1. The three angles amount to 180°, or two right angles.

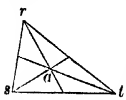
2. Any exterior angle, as A C *n*, is equal to the two interior and opposite ones, A and B.

3. The greater side is opposite the greater angle.

4. The sides are as the sines of the opposite angles. Thus, the side *a* is to the side *b* as the sine of A is to the sine of B.

5. If any angle as *s* be bisected by a line *s o*, the two parts *m o*, *o n* of the opposite side *m n* will be to each other as the other two sides *s m*, *s n*, or, *m o* : *o n* :: *s m* : *s n*.

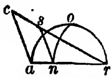




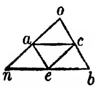
6. If lines be drawn from each angle *r s t* to the center of the opposite side, they will cross each other at one point, *a*, and the short part of each of the lines will be the third part of the whole line. Also, *a* is the **cen of grav** of the triangle.

7. If lines be drawn bisecting the three angles, they will meet at a point perpendicularly equidistant from each side, and consequently the **center of the greatest circle** that can be drawn in the triangle.

8. If a line *s n* be drawn parallel to any side *c a*, the two triangles *r s n*, *r c a*, will be similar.

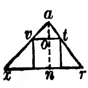


9. To divide any triangle *a c r* into two equal parts by a line *s n* parallel to any one of its sides *c a*. On either one of the other sides, as *a r*, as a diam, describe a semicircle *a o r*; and find its middle *o*. From *r* (opposite *c a*), with radius *r o*, describe the arc *o n*. From *n* draw *n s*, parallel to *c a*.



10. To find the greatest parallelogram that can be drawn in any given triangle *o n b*. Bisect the three sides at *a c e*, and join *a c*, *a e*, *e c*. Then either *a e b c*, *a e c o*, or *a c e n*, each equal to half the triangle, will be the reqd parallelogram. Any of these parallelograms can plainly be converted into a rectangle of equal area, and the greatest that can be drawn in the triangle.

10½. If a line *a c* bisects any two sides *o b*, *o n*, of a triangle, it will be parallel to the third side *n b*, and half as long as it.



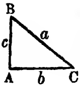
11. To find the greatest square that can be drawn in any triangle *a x r*. From an angle as *a* draw a perp *a n* to the opposite side *x r*, and find its length. Then *v n*, or a side *v t* of the square $= \frac{x\,r \times a\,n}{x\,r + a\,n}$

Rem.—If the triangle is such that two or three such perps can be drawn, then two or three equal squares may be found.

Right-angled Triangles.

All the foregoing apply also to right-angled triangles; but what follow apply to them only.

Call the right angle A, and the others B and C; and call the sides respectively opposite to them a, b, and c. Then is



$$a = \frac{c}{\text{Sine C}} = c \times \text{Sec B} = \frac{b}{\text{Cosine C}} = b \times \text{Sec C} = \sqrt{b^2 + c^2}$$

$b = a \times \text{Sine B} = a \times \text{Cos C} = c \times \text{Cot C} = c \times \text{Tang B}.$

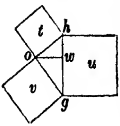
$c = a \times \text{Sine C} = a \times \text{Cos B} = b \times \text{Tang C}.$

Also Sine of $C = \frac{c}{a}$; Cos $C = \frac{b}{a}$; Tang $C = \frac{c}{b}$.

And Sine of $B = \frac{b}{a}$; Cos $B = \frac{c}{a}$; Tang $B = \frac{b}{c}$.

And Sine of A or $90^\circ = 1$. Cos $A = 0$. Tang A = infinity. Sec A = infinity.

1. If from the right angle o a line $o\,w$ be drawn perp to the hypothenuse or long side $h\,g$, then the two small triangles $o\,w\,h$, $o\,w\,g$, and the large one $o\,h\,g$, will be similar. Or $g\,w : w\,o :: w\,o : w\,h$; and $g\,w \times w\,h = w\,o^2$.



2. A line drawn from the right angle to the **center** of the long side will be half as long as said side.

3. If on the three sides $o\,h$, $o\,g$, $g\,h$ we draw three squares t, u, v, or three circles, or triangles, or any other three figs that are similar, then the area of the largest one is equal to the sum of the areas of the two others.

4. In a triangle whose sides are as 3, 4, and 5 (as are those of the triangle A B C), the angles are very approximately 90°; $53^\circ\ 7'\ 48.38''$; and $36^\circ\ 52'\ 11.62''$. Their Sines, 1.; .8; and .6. Their Tangs, infinity; 1.3333; and .75.

5. One whose sides are as 7, 7, and 9.9, has very approx one angle of 90° and two of 45° each, near enough for all practical purposes.

PROBLEMS IN SURVEYING.

Plane trigonometry teaches how to find certain unknown parts of plane, or straight-sided triangles, by means of other parts which are known; and thus enables us to measure inaccessible distances, &c. A triangle consists of six parts, namely, three sides, and three angles; and if we know any three of these, (except the three angles, and in the ambiguous case under "Case 2,") we can find the other three. The following four cases include the whole subject; the student should commit them to memory.

Case 1. Having any two angles, and one side, to find the other sides and angle.

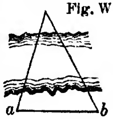


Fig. W

Add the two angles together; and subtract their sum from 180°; the rem will be the third angle. And for the sides, as

Sine of the angle opp the given side : Sine of the angle opp the reqd side :: given side : reqd side.

Use the side thus found, as the given one; and in the same manner find the third side.

Case 2. Having two sides, $b\,a$, $a\,c$, Fig X, and the angle $a\,b\,c$, opposite to one of them, to find the other side and angles.

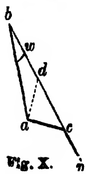

Fig. X.

Side $a\,c$ opp the given angle $a\,b\,c$: The other given side $b\,a$ :: Sine of the given angle $a\,b\,c$: Sine of angle $b\,d\,a$ or $b\,c\,a$ opposite the other given side $b\,a$.

Having found the sine, take out the corresponding angle from the table of nat sines, but, in doing so, if the side $a\,c$ opp the given angle is shorter than the other given side $b\,a$, bear in mind that an angle and its supplement have the same sine. Thus, in Fig X, the sine, as found above, is opp the angle $b\,c\,a$ in the table. But $a\,c$, if *shorter than* $b\,a$, can evidently be laid off in the opp direction, $a\,d$, in which case $b\,d\,a$ is the supplement of $b\,c\,a$. If $a\,c$ is as long as, or longer than, $b\,a$, there can be no doubt; for in that case it cannot be drawn toward b, but only toward n, and the angle $b\,c\,a$ will be found at once in the table, opp the sine as found above.

When the two angles, *a b c*, *b c a*, have been found, find the remaining side by Case 1.
For the remaining angle, *b a c*, add together the angle *a b c* first given, and the one, *b c a*, found as above. Deduct their sum from 180°.

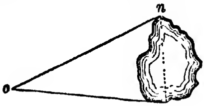
Case 3. Having two sides, and the angle included between them.

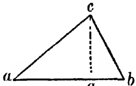
Take the angle from 180°; the rem will be the sum of the two unknown angles. Div this sum by 2; and find the nat tang of the quot. Then as

The sum of the two given sides : Their diff : : Tang of half the sum of the two unknown angles : Tang of half their diff.

Take from the table of nat tang, the angle opposite this last tang. Add this angle to the half sum of the two unknown angles, and it will give the angle opp the longest given side; and subtract it from the same half sum, for the angle opp the shortest given side. Having thus found the angles, find the third side by Case 1.

As a practical example of the use of Case 3, we can ascertain the dist *n m* across a deep pond, by measuring two lines *n o* and *m o*; and the angle *n o m*. From these data we may calculate *n m*; or by drawing the two sides, and the angle on paper, by a scale, we can afterward measure *n m* on the drawing.





Case 4. Having the three sides.

To find the three angles; upon one side *a b* as a base, draw (or suppose to be drawn) a perp *c g* from the opposite angle *c*. Find the diff between the other two sides, *a c* and *c b*; also their sum. Then, as

The base : Sum of the other two sides : : Diff of other two sides : Diff of the two parts *a g* and *b g*, of the base.

Add *half* this diff of the parts, to *half* the base *a b*; the sum will be the longest part *a g*; which taken from the whole base, gives the shortest part *g b*. By this means we get in each of the small triangles *a c g* and *c g b*, two sides, (namely, *a c* and *a g*; and *c b* and *g b*;) and an angle (namely, the right angle *c g a*, or *c g b*) opposite to one of the given sides. Therefore, use Case 2 for finding the angles *a* and *b*. When that is done, take their sum from 180°, for the angle *a c b*.

Or, 2d mode; call **half** the sum of the three sides, **s**; and call the two sides which form either angle, **m** and **n**. Then the nat sine of **half** that angle will be equal to $\sqrt{\dfrac{(s-m)\times(s-n)}{m\times n}}$.

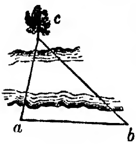


Fig. 1.

Ex. 1. To find the dist from *a* to an inaccessible object *c*.

Measure a line *a b*; and from its ends measure the angles *c a b* and *c b a*. Thus having found one side and two angles of the triangle *a b c*, calculate *a c* by means of Case 1. Or if extreme accuracy is not reqd, draw the line *a b* on paper to any convenient scale; then by means of a protractor lay off the angles *c a b*, *c b a*; and draw *a c* and *c b*; then measure *a c* by the same scale.

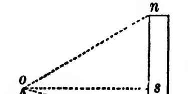

Fig. 2.

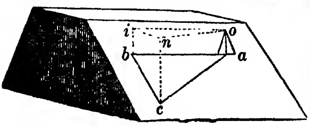
Ex. 2. To find the height of a *vertical* object, *n a*.

Place the instrument for measuring angles, at any convenient spot *o*; also meas the dist *o a*; or if *o a* cannot be actually measd in consequence of some obstacle, calculate it by the same process as *a c* in Fig 1. Then, first directing the instrument horizontally,* as *o s*, measure the angle of depression, *s o a*, say 12°; also the angle *s o n*, say 30°. These two angles added together, give the angle *a o n*, 42°. Now, in the small triangle *o s a* we have the angle *o s a* equal to 90°, because *a n* is vert, and *o s* hor; and since the three angles of any triangle are equal to 180°, if we subtract the angles *o s a* (90°), and *s o a* (12°) from 180°, the rem (78°) will be the angle *o a s* or *o a n*. Therefore, in the triangle *o n a*, we have one side *o a*; and two angles *a o n*, and *o a n*, to calculate the side *a n* by Case 1.

* **Angles and dists on sloping ground must be measured horizontally.** The graduated hor circle of the instrument evidently measures the angle between two objects horizontally, no matter how much higher one of them may be than the other; one perhaps requiring the telescope of the instrument to be directed upward toward it; and the other downward. If, therefore, the sides of triangles lying upon sloping ground, are not also measd hor, there can be no accordance between the two. Thus



Rem. If, as in Fig 3, it should be necessary to ascertain the *vert* height $a\,n$ from a point o, entirely above it, then both the angles measd at o, namely, $s\,o\,n$, and $s\,o\,a$, will be angles of depression, or *below* the hor line $o\,s$ assumed to measure them from. In this case we have the side $o\,a$ as before; the angle $n\,o\,a = s\,o\,a - s\,o\,n$; and the angle $o\,a\,n = 180^\circ - \left(o\,s\,a\ (90^\circ),\text{ and } s\,o\,a;\right)$ to calculate $a\,n$ by Case I.

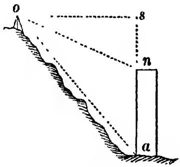


Fig. 3.

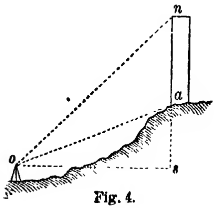

Fig. 4.

Or if, as in Fig 4, the observations are to be taken from a point o, entirely below the object $a\,n$, then both the angles $s\,o\,a$, $s\,o\,n$, will be angles of elevation, or *above* the assumed hor line $o\,s$. Here we have in the triangle $o\,n\,a$, the given side $o\,a$ as before; the angle $a\,o\,n = s\,o\,n - s\,o\,a$; and the angle $o\,n\,a = 180^\circ - \left(o\,s\,n\ (90^\circ),\text{ and } n\,o\,s,\right)$ to calculate $a\,n$ by Case 1

If the object $a\,n$, as in Fig 5, instead of being *vert*, is *inclined*, and instead of its vert height we wish to find its length $a\,n$, we must first ascertain its angle $y\,t\,i$ of inclination to the horizon, to which angle each of the angles $o\,s\,n$ will be equal. To find this angle $y\,t\,i$, suspend a plumb line $i\,y$, of any convenient known length, from the object $a\,n$, and measure also $y\,t$ horizontally Then say as

$$y\,t : i\,y :: 1 : \text{nat tang of angle } y\,t\,i.$$

From the table of nat tangs take out the angle $y\,t\,i$ found opposite this nat tang, and use it for the angles $o\,s\,n$ or $o\,s\,a$; instead of the 90° of Figs 3 and 4. Also when the object inclines, the side $a\,o$ of the triangle must be measd in line, or in range with the inclination. If the object, as the rock $a\,n$, Fig 6, is curved or irregular, a pole $a\,s$ may be planted sloping in the direction $a\,n$; and

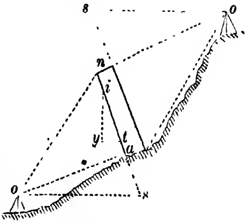

Fig. 5.

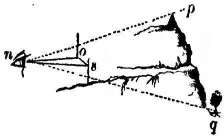
---

in the triangle $a\,b\,c$, upon sloping ground, the instrument at o measures the hor angle $s\,o\,n$, and not the angle $b\,a\,c$. Therefore, the side which corresponds with this hor angle $s\,o\,n$, is the hor dist $t\,n$; and not the sloping dist $b\,c$. In other words, when sides and angles are on sloping ground, we do not seek their *actual* measures; but their *hor* ones. This remark applies to all surveying for farms railroads, triangulations of countries, &c, &c; and the want of a strict attention to it, is one cause of the small errors, almost unavoidable, (and fortunately, of but trifling consequence in practice), which occur in all ordinary field operations.

When a sextant is used, angles between objects at diff altitudes, as p and q, may be measd hor, by first planting two vert rods o and s, in range with the objects; and then taking the hor angle $o\,n\,s$, subtended by the rods.

Angles may be measd without any inst, thus: Measure 100 ft toward each object, and drive stakes; measure the dist across from one stake to the other. Half this dist will be the sine of *half* the angle to a rad of 100; and if we move the decimal point two places to the left, we get the *nat sine* of this one half of the angle to a rad of 1, as in the tables. Thus, suppose the dist to be 80.64 feet, then 40.32 is the sine of half the angle; and .4032 will be the nat sine, opposite to which in the table of nat sines we find the angle 23° 47′; which mult by 2 gives 57° 34′, the reqd angle. If obstacles prevent measuring *toward* the objects, we may measure directly *from* them; because, when two lines intersect, the opposite angles are equal. A rough measurement may be made by sticking three pins vert, and a few ins apart, into a small piece of board, nailed hor to the top of a post. The pins would occupy the positions $n\,o\,s$, of the last figure. Pencil-lines may then be drawn, connecting the pin-holes; and the angle be measd with a protractor. By nailing a piece of board vert to a tree, and then drawing upon it a short hor line, by means of a pocket carpenters' spirit-level, vert angles of elevation and depression may be taken roughly in the same way In this way the writer has at times availed himself of the outer door of a house, by opening it until it pointed toward some mountain-peak, the dist of which he knew approximately; but of the height of



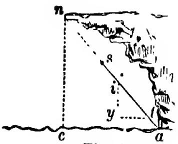


Fig. 6.

its angle *y t i* of inclination with the horizon found as before; in which case the dist *a n* is calculated. Or if the vert height *c n* is sought, the point *c* may first be found by sighting upward along a plumb-line held above the head.

Ex. 3. To find the approximate height, *s x*, of a mountain,

Of which, perhaps, only the very summit, *x*, is visible above interposing forests, or other obstacles, but the dist, *m i*, of which is known. In this case, first direct the instrument hor, as *m h*; and then measure the angle *i m x*. Then in the triangle *i m x* we have one side *m i*, the meas'd angle *i m x*, and the angle *m i x* (90°), to find *i x* by Case 1. But to this *i x* we must add *i o*, equal to the height *y m* of the instrument above the ground, and also *o s*. Now, *o s* is *apparently* due entirely to the curvature of the earth, which is equal to very nearly 8 ins, or .667 ft in one mile, and increases as the squares of the dists, being 4 times 8 ins in 2 miles, 9 times 8 ins in 3 miles, &c. But this is somewhat diminished by the refraction of the atmosphere; which varies with temperature, moisture, &c, but **always** tends to make the object *x* appear higher than it actually is. At an average, this deceptive elevation amounts to about $\frac{1}{7}$th part of the curvature of the earth; and like the latter, it varies with the squares of the dists. Consequently if we subtract $\frac{1}{7}$ part from 8 ins, or .667 ft, we have at once the combined effect of curvature and refraction for one mile, equal to 6.857 ins, or .5714 ft, and for other dists, as shown in the following table, by the use of which we avoid the necessity of making *separate* allowances for curvature and refraction.

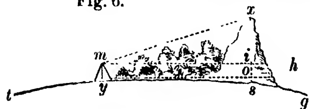

Fig. 7.

Table of allowances to be added for curvature of the earth; and for refraction; combined.

Dist. in yards.	Allow. feet	Dist. in miles.	Allow. feet	Dist. in miles.	Allow. feet.	Dist. in miles	Allow. feet.
100	.002	¼	.036	6	20.6	20	229
150	.004	½	.143	7	28.0	22	277
200	.007	¾	.321	8	36.6	25	357
300	.017	1	.572	9	46.3	30	514
400	.030	1¼	.893	10	57.2	35	700
500	.046	1½	1.29	11	69.2	40	915
600	.066	1¾	1.75	12	82.3	45	1158
700	.090	2	2.29	13	96.6	50	1429
800	.118	2½	3.57	14	112	55	1729
900	.149	3	5.14	15	129	60	2058
1000	.185	3½	7.00	16	146	70	2801
1200	.266	4	9.15	17	165	80	3659
1500	.415	4½	11.6	18	185	90	4631
2000	.738	5	14.3	19	206	100	5717

Hence, if a person whose eye is 5.14 ft, or 112 ft above the sea, sees an object just at the sea's horizon, that object will be about 3 miles, or 14 miles distant from him.

A horizontal line is not a level one, for a straight line cannot be a level one. The curve of the earth, as exemplified in an expanse of quiet water, is level. In Fig 7, if we suppose the curved line *t y s g* to represent the surface of the sea, then the points *t y s* and *g* are on a level with each other. They need not be equidistant from the center of the earth, for the sea at the poles is about 13 miles nearer it than at the equator; yet its surface is everywhere on a level. **Up, and down,** refer to sea level. **Level** means parallel to the curvature of the sea; and **horizontal** means tangential to a level.

Ex. 4. If the inaccessible vert height *c d*, Fig 8,

is so situated that we cannot reach it at all, then place the instrument for measuring angles, at any convenient spot *n*; and in range between *n* and *d*, plant two staffs, whose tops *o* and *i* shall range precisely with *n*, though they need not be on the same level or hor line with it. Measure *n o*: also from *n* measure the angles *o n d* and *o n c*. Then move the instrument to the precise spot previously

---

which he had no idea. For allowance for curvature and refraction see above Table.

A triangle whose sides are as 3, 4, and 5, is right angled; and one whose sides are as 7, 7; and 9.9; contains 1 right angle; and 2 angles of 45° each. As it is frequently necessary to lay down angles of 45° and 90° on the ground, these proportions may be used for the purpose, by shaping a portion of a tape-line or chain into such a triangle, and driving a stake at each angle.

occupied by the top o of the staff; and from o measure the angles $i\,o\,d$ and $d\,o\,c$. This being done, subtract the angle $i\,o\,c$ from 180°; the rem will be the angle $c\,o\,n$. Consequently in the triangle $n\,o\,c$, we have one side $n\,o$, and two angles, $c\,n\,o$ and $c\,o\,n$, to find by Case 1 the side $o\,c$. Again, take the angle $i\,o\,d$ from 180°; the remainder will be the angle $n\,o\,d$, so that in the triangle $d\,n\,o$ we have one side $n\,o$, and the two angles $d\,n\,o$ and $n\,o\,d$, to find by Case 1 the side $o\,d$. Finally, in the triangle $c\,o\,d$, we have two sides $c\,o$ and $o\,d$, and their included angle $c\,o\,d$, to find $c\,d$, the reqd vert height.

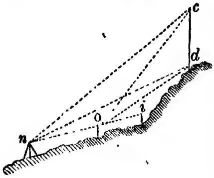

Fig. 8.

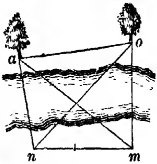

Fig. 9.

Rem. If $c\,d$ were in a valley, or on a hill, and the observations reqd to be made from either higher or lower ground, the operation would be precisely the same.

Ex. 5. See Ex 10.

To find the dist *a o*, Fig 9, between two entirely inaccessible objects,

Measure a side $n\,m$; at n measure the angles $a\,n\,m$ and $o\,n\,m$; also at m measure the angles $o\,m\,n$, and $a\,m\,n$. This being done, we have in the triangle $a\,n\,m$, one side $n\,m$, Fig 9, and the angles $a\,n\,m$, and $n\,m\,a$; hence, by Case 1, we can calculate the side $a\,n$. Again, in the triangle $o\,m\,n$ we have one side $n\,m$, and the two angles $o\,m\,n$, and $m\,n\,o$; hence, by Case 1, we can calculate the side $n\,o$. This being done, we have in the triangle $a\,n\,o$, two sides $a\,n$, and $n\,o$; and their included angle $a\,n\,o$; hence, by Case 3, we can calculate the side $a\,o$, which is the reqd dist. It is plain that in this manner we may obtain also the position or direction of the inaccessible line $a\,o$; for we can calculate the angle $n\,a\,o$; and can therefrom deduce that of $a\,o$; and thus be enabled to run a line parallel to it, if required. By drawing $n\,m$ on paper by a scale, and laying down the four measd angles, the dist $a\,o$ may be measd upon the drawing by the same scale.

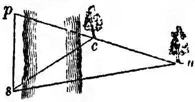

Fig. 10.

If the position of the inaccessible dist $c\,n$, Fig 10, be such that we can place a stake p in line with it, we may proceed thus. Place the instrument at any suitable point s, and take the angles $p\,s\,c$ and $c\,s\,n$. Also find the angle $c\,p\,s$, and measure the dist $p\,s$. Then in the triangle $p\,s\,c$ find $s\,c$ by Case 1; again, the exterior angle $n\,c\,s$, being equal to the two interior and opposite angles $c\,p\,s$, and $p\,s\,c$, we have in the triangle $c\,s\,n$, one side and two angles to find $c\,n$ by Case 1.

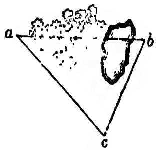

Fig. 11.

Ex. 6. To find a dist *a b*, Fig 11, of which the ends only are accessible.

From a and b, measure any two lines $a\,c$, $b\,c$, meeting at c; also measure the angle $a\,c\,b$. Then in the triangle $a\,b\,c$ we have two sides, and the included angle, to find the third side $a\,b$ by Case 3.

Ex. 7. To find the vert height *o m*, of a hill, above a given point *i*.

Place the instrument at i; measure $a\,m$. Directing the instrument hor, as $a\,n$, take the angle $n\,a\,m$. Then, since $a\,n\,m$ is 90° Fig 12, we have one side $a\,m$, and two angles, $n\,a\,m$ and $a\,n\,m$, to find $n\,m$ by Case 1. Add $n\,o$, equal to $a\,i$, the height of the instrument. Also, if the hill is a long one, add for curvature of the earth, and for refraction, as explained in Example 3, Fig 7. Or the instrument may be placed at the top of the hill; and an angle of depression measured; instead of the angle of elevation $n\,a\,m$.

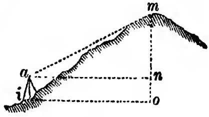

Fig. 12.

Rem. 1. It is plain, that if the height $o\,m$ be previously known, and we wish to ascertain the dist from its summit m to any point i, the same measurement as before, of the angle $n\,a\,m$, will enable us to calculate $a\,m$ by Case 1. So in Ex. 2, if the height $n\,a$ be known, the angles measd in that example, will enable us to compute the dist $a\,o$; so also in Figs 3, 4, 5, and 7; in all of which the process is so plain as to require no further explanation.

Rem. 2. The height of a vert object **by means of its shadow.** Plant one end of a straight stick vert in the ground; and measure its shadow; also measure the length of the shadow of the object. Then, as the length of the shadow of the stick is to the length of the stick above

ground, so is the length of the shadow of the object, to its height. If the object is inclined, the stick must be equally inclined.

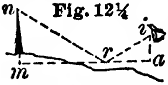

Fig. 12¼

Rem. 3. Or the height of a vert object mn, Fig 12¼, whose distance rm is known, may be found **by its reflection** in a vessel of water, or in a piece of looking glass placed perfectly horizontal at r; for as ra is to the height ai of the eye above the reflector r, so is rm to the height mn of the object above r.

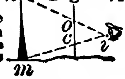

Fig. 12½

Rem. 4. Or let oc, Fig 12½, **be a planted pole,** or a rod held vert by an assistant. Then stand at a proper dist back from it, and keeping the eyes steady, let marks be made at o and c, where the lines of sight in and im strike the rod. Then as ic is to co, so is im to mn.

The following examples may be regarded as substitutes for strict trigonometry · and will at times be useful, in case a table of sines, &c, is not at hand for making trigonometrical calculations.

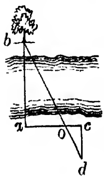

Fig. 13.

Ex. 8. To find the dist ab, **of which one end only is accessible.**

Drive a stake at any convenient point a, from a lay off any angle bac. In the line ac, at any convenient point c, drive a stake, and from c lay off an angle acd, equal to the angle bac. In the line cd, at any convenient point, as d, drive a stake. Then, standing at d, and looking at b, place a stake o in range with db, and at the same time in the line ac. Measure ao, oc, and cd; then, from the principle of similar triangles, as

$$oc : cd :: ao : ab.$$

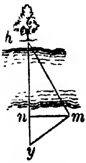

Fig. 14.

Or thus:

Fig 14, nh being the dist, place a stake at n; and lay off the angle hnm 90°. At any convenient dist nm, place a stake m Make the angle $hmy = 90°$; and place a stake at y, in range with hn. Measure ny and nm; then, from the principle of similar triangles, as

$$ny : nm :: nm : nh.$$

Or thus, Fig 14. Lay off the angle $hnm = 90°$, placing a stake m, at any convenient dist nm. Measure nm. Also measure the angle nmh. Find nat tang of nmh by Table Mult this nat tang by nm. The prod will be nh.

Or thus. Lay off angle $hnm = 90°$. From m measure the angle nmh, and lay off angle nmy equal to it, placing a stake at y in range with hn. Then is $ny = nh$.

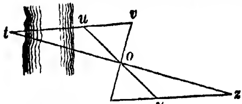

Fig. 15.

Or thus, without measuring any angle;

tu being the dist. Make uv of any convenient length, in range with tu. Measure any vo; and ox equal to it, in range Measure uo; and oy equal to it in range. Place a stake z in range with both xy, and to. Then will yz be both equal to tu, and parallel to it.

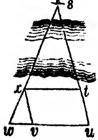

Fig. 16.

Or thus, without measuring any angle.

Drive two stakes t and u, in range with the object s. From t lay off any convenient dist tx, in any direction From u lay off uw parallel to tx, placing w in range with xs. Make uv equal to tx. Measure wv, vx, and xt. Then, as

$$wv : vx :: xt : ts.$$

Or thus. At a lay off angle $oac = 5° 43'$. Lay off oc at right angles to ao. Measure oc. Then $ao = 10\,oc$, too long only 1 part in 935.6, or 5.643 feet in a mile, or .1069 foot (full 1¼ inches) in 100 feet.

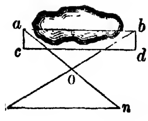

Fig. 17.

Ex. 9. To find the dist *a b*, of which the ends only are accessible.

From *a* lay off the angle *b a c*; and from *b*, the angle *a b d* each 90°. Make *a c* and *b d* equal to each other. Then, *c d* = *a b*. Or *a b* may be considered as the dist across the river in Figs 15, 13, or 14; and be ascertained in the same way. Or measure any dist, Fig 17, *a o*, and make *o n* in line and equal to it. Also measure *b o*; and make *o m* in line and equal to it. Then will *m n* be both parallel to *a b*, and equal to it.

Ex. 10. See Ex. 4. **To find the entirely inaccessible dist *y z*, and also its direction.**

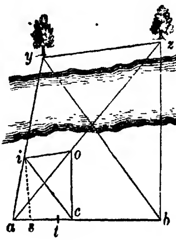

Fig. 18.

At any two convenient points *a* and *b*, from each of which and *z* can be seen, drive stakes. Then we have the four rners of a four sided figure, in which are given the directions ' three of its sides, and of its two diags. These data enable us lay out on the ground, the small four-sided fig *a c o i*, exactly milar to the large one. Thus, in the line *a b* place a stake ; and make *c o* parallel to *b z*; *o* being at the same time in inge of the diag *a z*. Also, from *c* make *c i* parallel to *b y*; being at the same time in range of *a y*. Then will *i o* be in ie same direction as *y z*, or parallel to it. Measure *a c*, *a b*, id *i o*; then evidently, from the principle of similar figures, as

***a c* : *a b* : : *i o* : *y z*.**

If *y z* were a visible line such as a fence or road, we could om *a* divide it into any required portions. Thus, if we wish place a stake halfway between *y* and *z*, first place one half-ay between *i* and *o*, then standing at *a*, by means of signals, ace a person in range on *y z*. Or, to find along *a b*, a point *t* erp to *y z* at *y*, first make *o i s* = 90°, and measure *a s*. Then,

***o i* : *a s* : : *y z* : *a t*.**

Ex. 11. To find the position of a point, *n*, Fig 19,

y means of two angles a n b *and* b n c, *taken from* n *to the three objects* a b c, *whose positions and dists apart are known*

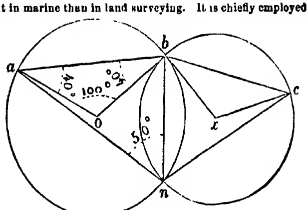

Fig. 19.

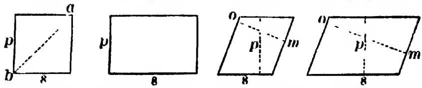
The use of this problem is more frequent in marine than in land surveying. It is chiefly employed or determining the position *n* of a oat from which soundings are being aken along a coast. As the boat moves from point to point to take resh soundings, it becomes necessary make a fresh observation at each oint, in order to define its position n the chart. An observation consists n the measurement by a sextant of ie two angles *a n b*, *b n c*, to the sig-als *a b c*, previously arranged on the hore. When practicable, this method hould be rejected; and the observa-ons taken to the boat at the same istant, by two observers on shore, at wo of the stations. The boat to show signal at the proper moment. The ost expeditious mode of fixing the oint *n* upon the map, is to draw three nes, forming the two angles, and ex-nded indefinitely, on a piece of trans-arent paper. Place the paper upon the map, and move it about until the three lines pass through ie three stations, then prick through the point *n* wherever it happens to come.

Instead of the transparent paper, an instrument called a *station pointer* may be used when there re many points to be fixed.

But the position of the point *n* can be found more correctly by describing two circles, as in Fig 19, ach of which shall pass through *n* and two of the station points. The question is to find the centers and *x* of two such circles. This is very simple. We know that the angle *a o b* at the center of a circle is vice as great as any angle *a n b* at the circumf of the same circle, when both are subtended by the ame chord *a b*. Consequently, if the angle *a n b*, observed from the boat is say, 50°, the angle *a o b* must be 100°. And, since the three angles of every plane triangle are equal to 180°, the two angles *a b* and *o b a* are together equal to 180° — 100° = 80°. And, since the two sides *a o* and *b o* are qual (being radii of the same circle), therefore, the angles *o a b* and *o b a* are equal, and each equal to $\frac{80}{2}$ = 40°. Consequently, on the map we have only to lay down at *a* and *b*, two angles of 40°; the oint *o* of intersection will be the center of the circle *a b n*. Proceed in the same way with the angle *n c*, to find the center *x*. Then the intersection of the two circles at *n* will be the point sought.

PARALLELOGRAMS.



A PARALLELOGRAM is any figure of four straight sides, the opposite ones of which are parallel. There are but four, as in the above figs. The rhombus, like the rhombohedron, Fig 3, p 195, is sometimes called "rhomb." In the square and rhombus all the four sides are equal; in the rectangle and rhomboid only the opposite ones are equal. In any parallelogram the four angles amount to four right angles, or 360°; and any two diagonally opposite angles are equal to each other; hence, having one angle given, the other three can readily be found. In a square, or a rhombus, a diag divides each of two angles into two equal parts; but in the two other parallelograms it does not.

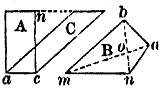
To find the area of any parallelogram.

Multiply any side, as S, by the perp height, or dist p to the opposite side. **Or,** multiply together two sides and nat sine of their included angle.

The diag a b of any square is equal to one side mult by 1.41421, and a side is equal to $\frac{\text{diagonal}}{1.41421}$, **or,** to diag mult by .707107.

The side of a square equal in area to a given circle, is equal to diam × .886227.

The side of the greatest square, *that can be inscribed in a given circle,* is equal to diam × .707107

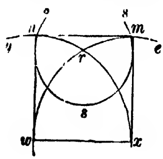


The side of a square mult by 1.51967 gives the **side of an equilateral triangle** of the same area. **All parallelograms** as A and C, **which have equal bases,** $a\ c$, and equal perp heights $n\ c$, have also equal areas, and the area of each is twice that of a triangle having the same base, and perp height. **The area of a square inscribed in a circle** is equal to twice the square of the rad

In every parallelogram, the 4 squares drawn on its sides have a united area equal to that of the two squares drawn on its 2 diags. **If a larger square** be drawn on the diag $a\ b$ of a smaller square its area will be twice that of said smaller square. **Either diag of any parallelogram** divides it into two equal triangles, and the 2 diags div it into 4 triangles of equal areas. **The two diags of any parallelogram** divide each other into two equal parts. **Any line drawn through the center of a diag** divides the parallelogram into two equal parts

Remark 1.—The area of any fig whatever as B **that is enclosed by four straight lines,** may be found thus. Mult together the two diags $a\ m$, $n\ b$; and the nat sine of the least angle $a\ o\ b$; or $n\ o\ m$, formed by their intersection. Div the product by 2. This is useful in land surveying when obstacles, as is often the case, make it difficult to measure the sides of the fig or field; while it may be easy to measure the diags; and after finding their point of intersection o, to measure the required angle. **But if the fig is to be drawn,** the **parts** $o\ a$, $o\ b$, $o\ n$, $o\ m$ of the diags must also be measd.

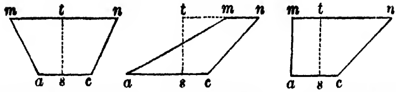
Rem. 2.—The sides of a parallelogram, triangle, and many other figs may be found, when only the area and angles are given, thus: Assume some particular one of its sides to be of the length 1; and calculate what its area would be if that were the case. Then as the sq rt of the area thus found is to this side 1, so is the sq rt of the actual given area, to the corresponding actual side of the fig.



On a given line $w\ x$, to draw a square $w\ x\ n\ m$.

From w and x, with rad $w\ x$, describe the arcs $x\ r\ y$ and $w\ r\ e$. From their intersection r, and with rad equal to ½ of $w\ x$, describe $s\ s\ s$. From w and x draw $w\ n$ and $x\ m$ tangential to $s\ s\ s$, and ending at the other arcs; join $n\ m$.

TRAPEZOIDS.

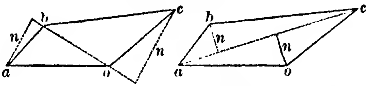


A trapezoid *a c n m*, is any figure with four straight sides, only two of which, as *ac* and *n m*, are parallel.

To find the area of any trapezoid.

Add together the two parallel sides, *a c* and *m n*; mult the sum by the perp dist *s t* between them; div the prod by 2. See the following rules for trapeziums, which are all equally applicable to trapezoids; also see Remarks after Parallelograms.

TRAPEZIUMS.



A trapezium *a b c o*, is any fig with four straight sides, of which no two are parallel.

To find the area of any trapezium, having given the diag *b o*, or *a c*, between either pair of opposite angles; and also the two perps, *n*, *n*, from the other two angles.

Add together these two perps; mult the sum by the diag; div the prod by 2.

Having the four sides; and either pair of opposite angles, as *a b c*, *a o c*; or *b a o*, and *b c o*.

Consider the trapezium as divided into two triangles, in each of which are given two sides and the included angle. Find the area of each of these triangles as directed under the preceding head "Triangles," and add them together.

Having the four angles, and either pair of opposite sides.

Begin with one of the sides, and the two angles at its ends. If the sum of these two angles exceeds 180°, subtract each of them from 180°, and make use of the rems instead of the angles themselves. Then consider this side and its two adjacent angles (or the two rems, as the case may be) as those of a triangle; and find its area as directed for that case under the preceding head "Triangle." Do the same with the other given side, and its two adjacent angles, (or their rems, as the case may be.) Subtract the least of the areas thus found, from the greatest, the rem will be the reqd area.

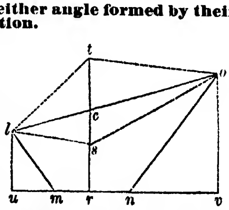
Having three sides; and the two included angles.

Mult together the middle side, and one of the adjacent sides, mult the prod by the nat sine of their included angle; call the result *a*. Do the same with the middle side and its other adjacent side, and the nat sine of the other included angle, call the result *b*. Add the two angles together; find the diff between their sum and 180°, whether greater or less, find the nat sine of this diff; mult together the two given sides which are *opposite* one another, mult the prod by the nat sine just found; call the result c. Add together the results *a* and *b*; then, if the sum of the two given angles is *less* than 180°, subtract *c* from the sum of *a* and *b*; *half* the rem will be the area of the trapezium. But if the sum of the two given angles be *greater* than 180°, add together the three results *a*, *b*, and *c*; *half* their sum will be the area.

Having the two diagonals, and either angle formed by their intersection.

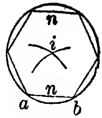
See Remarks after Parallelograms.

In railroad measurements



Of excavation and embankment, the trapezium *l m n o* frequently occurs; as well as the two 5-sided figures *l m n o t* and *l m n o s*; in all of which *m n* represents the roadway; *r s*, *r c*, and *r t* the center-depths or heights; *l u* and *o v* the side-depths or heights, as given by the level; *l m* and *n o* the side-slopes.

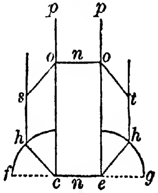
The same general rule for area applies to all three of these figs; namely, mult the extreme hor width *u v* by *half* the center depth *r s*, *r c*, or *r t*, as the case may be. Also mult one *fourth* of the width of roadway *m n*, by the *sum* of the two side-depths *l u* and *o v*. Add the two prods together; the sum is the reqd area. This rule applies whether the two side-slopes *m l* and *n o* have the same angle of inclination or not. **In railroad work, etc., the mid way hor width, center depth, and side depths of a prismoid are respectively = The half sums of the corresponding end ones, and thus can be found without actual measurement.**



To draw a hexagon, each side of which shall be equal to a given line, *a b*.

From *a* and *b*, with rad *a b*, describe the two arcs; from their intersection, *i*, with the same rad, describe a circle; around the circumf of which, step off the same rad.

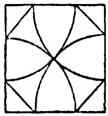
Side of a hexagon $= nn \times .57735$.



To draw an octagon, with each side equal to a given line, *c e*.

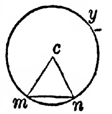
From *c* and *e* draw two perps, *c p*, *e p*. Also prolong *c e* toward *f* and *g*; and from *c* and *e*, with rad equal *c e*, draw the two quadrants; and find their centers *h h*; join *c h*, and *e h*; draw *h s* and *h t* parallel to *c p*; and make each of them equal to *c e*; make *c o*, and *e o*, each equal to *h h*; join *o o*, *o s*, and *o t*.

Side of an octagon $= nn \times .41421354$.



To draw an octagon in a given square.

From each corner of the square, and with a rad equal to half its diag, describe the four arcs; and join the points at which they cut the sides of the square.



To draw any regular polygon, with each side equal to *m n*.

Div 360 degrees by the number of sides; take the quot from 180°; div the rem by 2. This will give the angle *c m n*, or *c n m*. At *m* and *n* lay down these angles by a protractor: the sides of these angles will meet at a point, *c*, from which describe the circle *m n y*; and around its circumf step off dists equal to *m n*.

In any circle, *m n y*, to draw any regular polygon.

Div 360° by the number of sides; the quot will be the angle *m c n*, at the center. Lay off this angle by a protractor; and its chord *m n* will be one side; which step off around the circumf.

To reduce any polygon, as *a b c d e f a*, to a triangle of the same area.

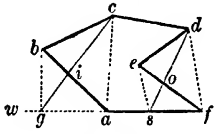


Fig. 1.

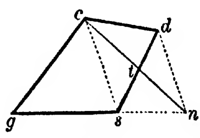

Fig. 2.

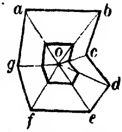
If we produce the side *f a* toward *w*; and draw *b g* parallel to *a c*, and join *g c*, we get equal triangles *a c b*, and *a c g*, both on the same base *a c*; and both of the same perp height, inasmuch as they are between the two parallels *a c* and *g b*. But the part *a c i* forms a portion of both these triangles, or in other words, *is common to both*. Therefore, if it be taken away from both triangles, the remaining parts, *i c b* of one of them, and *i g a* of the other, are also equal. Therefore, if the part *i c b* be left off from the polygon, and the part *i g a* be taken into it, the polygon *g f e d c i g* will have the same area as *a f e d c b a*; but it will have but five sides, while the other has six. Again, if *e s* be drawn parallel to *d f*, and *d s* joined, we have upon the same base *e s*, and between the same parallels *e s* and *d f*, the two equal triangles *e s d*, and *e s f*, with the part *e o s* common to both; and consequently the remaining part *e o d* of one, and *o s f* of the other, are equal. Therefore, if *o s f* be left off from the polygon, and *s o d* be taken into it, the new polygon *g s d c g*, Fig 2, will have the same area as *g f e d c g*; but it has but four sides, while the other has five. Finally, if *g s*, Fig 2, be extended toward *n*; and *d n* drawn parallel to *c s*; and *c n* joined, we have on the same base *c s*, and between the same parallels *c s* and *d n*, the two equal triangles *c s n*, and *c s d*, with the part *c s t* common to both. Therefore, if we leave out *c d t*, and take in *s t n*, we have the triangle *g n c* equal to the polygon *g s d c g*, Fig 2; or to *a f e d c b a*, Fig 1.

This simple method is applicable to polygons of any number of sides.

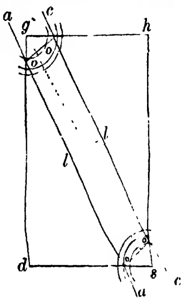


To reduce a large fig, *a b c d e f g*, to a smaller similar one.

From any interior point *o*, which had better be near the center, draw lines to all the angles *a*, *b*, *c*, &c. Join these lines by others parallel to the sides of the fig. If it should be reqd to enlarge a small fig, draw, from any point *o* within it, lines extending beyond its angles; and join these lines by others parallel to the sides of the small fig.

To reduce a map to one on a smaller scale.

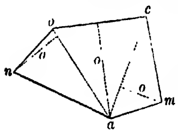
The best method is by dividing the large map into squares by faint lines, with a very soft lead pencil, and then drawing the reduced map upon a sheet of smaller squares. A pair of proportional dividers will assist much in fixing points intermediate of the sides of the squares. If the large map would be injured by drawing and rubbing out the squares, threads may be stretched across it to form the squares.



In a rectangular fig, *g h s d*,

Representing an open panel, to find the points *o o o o* in its sides; and at equal dists from the angles *g*, and *s*; for inserting a diag piece *o o o o*, of a given width *l l*, measured at right angles to its length. From *g* and *s* as centers, describe several concentric arcs, as in the Fig. Draw upon transparent paper, two parallel lines *a a*, *c c*, at a distance apart equal to *l l*, and placing these lines on top of the panel, move them about until it is shown by the arcs that the four dists *g o*, *g o*, *s o*, *s o* are equal. Instead of the transparent paper, a strip of common paper, of the width *l l* may be used.

REM. Many problems which would otherwise be very difficult, may be thus solved with an accuracy sufficient for practical purposes, **by means of transparent paper.**

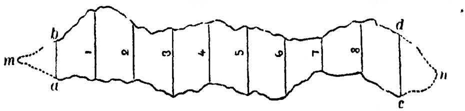


To find the area of any irregular polygon, *a n b c m*.

Div it into triangles, as *a n b*, *a m c*, and *a b c*, in each of which find the perp dist *o*, between its base *a b*, *a c*, or *b c*; and the opposite angle *n*, *m*, or *a*, mult each base by its perp dist; add all the prods together, div by 2.

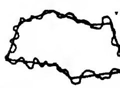
To find approx the area of a long irregular fig, as *a b c d*.

Between its ends *a b*, *c d*,



space off *equal* dists, (the shorter they are the more accurate will be the result,) through which draw the intermediate parallel lines 1, 2, 3, &c, across the breadth of the fig. Measure the lengths of these intermediate lines; add them together, to the sum add *half* the sum of the two end breadths *a b* and *c d*. Mult the entire sum by one of the equal spaces between the parallel lines. The prod will be the area. This rule answers as well if either one or both the ends terminate in points, as at *m* and *n*. In the last of these cases, both *a b* and *c d* will be included in the intermediate lines, and half the two end breadths will be 0, or nothing.

To find the area of any irregular figure.



Draw around it lines which shall enclose within them (as nearly as can be judged by the eye) as much space not belonging to the figure as they exclude space belonging to it. The area of the simplified figure thus formed, being in this manner rendered equal to that of the complicated one, may be calculated by dividing it into triangles, &c. By using a piece of fine thread, the proper position for the new boundary lines may be found, before drawing them in.

Areas of irregular figures may be found from a drawing, by laying upon it a piece of transparent paper carefully ruled into small squares, each of a given area, say 10, 20, or 100 sq. ft. each; and by first counting the whole squares, and then adding the fractions of squares.

CIRCLES.

A circle is the area included within a curved line, called the **circumference,** every point of which is equidistant from a fixed point, within the circle, called its **center.** Any straight line, passing entirely across the circle through its center, is called a **diameter** of the circle. Any straight line, extending from the center to the circumference, is called a **radius.**

The ratio of the circumference to the diameter, or of the semi-circumference to the radius, = circumf ÷ diam, is called π (**pi**).

$$\pi = 4\ (1 - 1/3 + 1/5 - 1/7 + 1/9 - \text{etc.}).$$

π is incommensurable; *i. e.*, it cannot be exactly stated arithmetically. It has been determined to several hundred places of decimals.

Approximate values of π; $\pi = x + x/a$:

x	a	x	a
3.141 592 653 6	— 307,788,000,000	355 ÷ 113	— 11,776,700
3.141 592 65	+ 875,085,000	377 ÷ 120	— 42,447
3.141 593	— 9,069,000	360 ÷ 114.6	+ 13,576
3.141 6	427,637	22 ÷ 7	— 2,485

Functions of π.

		Logarithm.			Logarithm.
π =	3.14159265	0.497 1499	$2/\pi$ =	0.636620	1.803 8801
$\pi/2$ =	1.57079632	0.196 1199	$3/\pi$ =	0.954930	1.979 9714
$\pi/3$ =	1.04719755	0.020 0286	π^2 =	9.869604	0.994 2997
$\pi\sqrt{2}$ =	4.442883	0.647 6649	π^3 =	31.00628	1.491 4496
$\pi/\sqrt{2}$ =	2.221442	0.346 6349	$\sqrt{\pi}$ =	1.772454	0.248 5749
$1/\pi$ =	0.318310	1.502 8501	$1/\sqrt{\pi}$ =	0.564190	1.751 4251

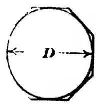
For multiples of π, see "Circumf," in tables, pp. 163 to 178.

Radius, R; Diameter, D; Circumference, C; Area, A.

$$R = \frac{D}{2} = \frac{C}{2\pi} = \sqrt{\frac{A}{\pi}}, \qquad D = 2R = \frac{C}{\pi} = 2\sqrt{\frac{A}{\pi}};$$

$$C = 2\pi R = \pi D = 2\sqrt{\pi A}; \qquad A = \pi R^2 = \frac{\pi}{4} D^2 = \frac{C^2}{4\pi} = \frac{DC}{4}.$$

RELATIONS OF CIRCLE TO OTHER FIGURES.



Circumscribed polygon, regular or irregular.

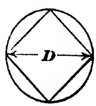
$$\frac{\text{Area of circle}}{\text{Area of polygon}} = \frac{\text{circumference of circle}}{\text{circumference of polygon}}.$$

Equilateral triangle of equal area. D = diam of circle.

Side of triangle = $D\sqrt{\pi} \div \sqrt[4]{3}$ = 1.34677 D.

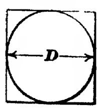
Square of equal area.

Side of square = 0.88623 × diam of circle.
Diam of circle = 1.12838 × side of square.



Inscribed square. D = diam of circle.

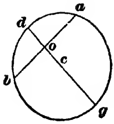
Side of square = $D\sqrt{\frac{1}{2}}$ = 0.7071 D.
Area of square = 2 × radius² of circle.
Radius of circle = ½ × diagonal of square
= $\sqrt{\frac{1}{2}}$ × side of square = 0.7071 × side.



Circumscribed square.

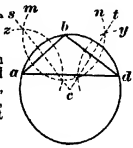
A = area of square; a = area of circle.

$$A = \frac{4}{\pi} a = 1.2732\, a; \qquad a = \frac{\pi}{4} A = 0.7854\, A.$$

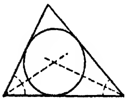


PROBLEMS IN CIRCLES.

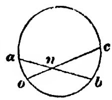
To find the diameter, $d\ g$, and the center, c, of a given circle.
Draw any chord $a\ b$; and from its middle, o, draw, at right angles to it, a diam $d\ g$; find the center c of this diam. Or see below.



To describe a circle through any three points, $a\ b\ d$, not in a straight line; *i. e.* through the three angles of a triangle.
Join the points by the lines $a\ b$, $b\ d$. From b, with any convenient rad, draw the arc $m\ n$; and from a and d, with the same rad, draw arcs y and z; then two lines, $c\ s$, $c\ t$, drawn through the intersections of these arcs, will bisect $a\ b$ and $b\ d$ perpendicularly, and will meet at the center, c, of the circle.



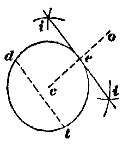
To inscribe a circle in a triangle, draw two lines bisecting any two of the angles. Where these lines meet is the center of the circle.



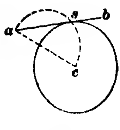
If **any two chords**, as $a\ b$, $o\ c$, cross each other, as at n; then as $o\ n : n\ b :: a\ n : n\ c$. Hence, $n\ b \times a\ n = o\ n \times n\ c$. That is, the product of the two segments of one of the chords is = the product of the two segments of the other chord.

Tangents.

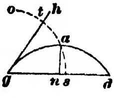
Here the "tangents" are merely straight lines, touching the circle, without cutting it; not trigonometrical tangents.



To draw a tangent, $i\ e\ i$, to a circle, through any given point, e, in its circumf.
Through the center c and the given point e, draw $c\ o$; make $e\ o = e\ c$; from c and o, with any rad greater than half of $o\ c$, describe the two pairs of arcs, i and i; join their intersections $i\ i$.
Or from e lay off any two equal distances $e\ d$, $e\ t$; and draw $i\ i$ parallel to $d\ t$.



To draw a tang, $a\ s\ b$, to a circle, from a point, a, which is outside of the circle.
Join $a\ c$, c being the center of the circle. On $a\ c$, describe a semi-circle; through the intersection, s, draw $a\ s\ b$.



To draw a tang, $g\ h$, from a circular arc, $g\ a\ d$, of which $n\ a$ is the rise. With rad $g\ a$, describe an arc, $s\ a\ o$. Make $t\ a = s\ a$. Through t draw $g\ h$.

TABLE 1 OF CIRCLES.
Diameters in units and eighths, &c.

Examples.

Diameter = 3.12699
Circumference = Sum of

Circ for dia of	3.1	=	9.738937
"	.02	=	.062832
"	.006	=	.018850
"	.0009	=	.002827
"	.00009	=	.000283
			9.823729

Circumfce = 9.823729
Diameter = Sum of

Dia for circ of	9.738937	=	3.1
	.084792		
"	.062832	=	.02
	.021960		
"	.018850	=	.006
	.003110		
"	.002827	=	.0009
	.000283		
"	.000283	=	.00009
			3.12699

TABLE 3 OF CIRCLES.

Diams in units and twelfths; as in feet and inches.

CIRCULAR ARCS.

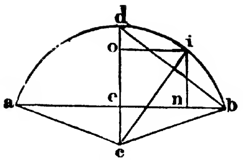

Fig.1

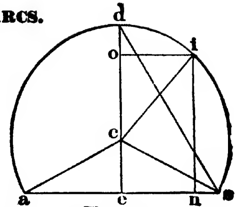

Fig. 2.

Rules for Fig. 1 apply to all arcs equal to, or less than, a semi-circle.
" " Fig. 2 " " " or greater than, a semi-circle.

Chord, *a b*, of whole arc, *a d b*,

$= 2 \times \sqrt{\text{radius}^2 - (\text{radius} - \text{rise})^2}$. Fig. 1.

$= 2 \times \sqrt{\text{radius}^2 - (\text{rise} - \text{radius})^2}$. Fig. 2.

$= 2 \times \sqrt{\text{rise} \times (2 \times \text{radius} - \text{rise})}$. Figs. 1 and 2.

$= 2 \times$ radius $\times$ sine of $\frac{1}{2}$ *a c b*. Figs. 1 and 2.

$= 2 \times \dfrac{\text{rise}}{\text{tangent of } a\,b\,d.*}$ Figs. 1 and 2.

$= 2 \times$ *d b* § $\times$ cosine of *a b d*.* Figs. 1 and 2.

$= 2 \times \sqrt{d\,b^2 - \text{rise}^2}$. Figs. 1 and 2.§

= approximately $8 \times$ *d b* § $- 3 \times$ length of arc *a d b* ¶. Fig. 1.

Length, *a d b*,

$= 2\,\pi$ radius $\times \dfrac{\text{arc } a\,d\,b \text{ in degrees}}{360}$. Figs. 1 and 2;

= .01745 $\times$ radius $\times$ arc *a d b* in degrees. Figs. 1 and 2.

= circumference of circle — length of *small* arc subtending angle *a c b*. Fig. 2.

= approximately $\dfrac{8 \times d\,b\,\S - \text{chord } a\,b.**}{3}$ Fig. 1.

---

* *a b d* is = $\frac{1}{4}$ of the angle *a c b*, subtended by the arc. In Fig. 2 the latter angle exceeds 180°.

§ *d b* = chord of *d i b*, or of half *a d b* $= \sqrt{\text{rise}^2 + (\frac{1}{2}\, a\, b)^2}$. Figs. 1 and 2.

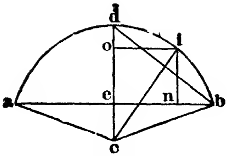

Fig.1

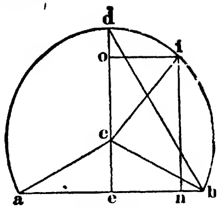

Fig. 2.

Continued from p. 179.

Rules for Fig. 1 apply to all arcs equal to or less than a semi-circle.
" " Fig. 2 " " " or greater than a semi-circle.

Radius, ca, cd, ci or cb,

$= \frac{(\frac{1}{2}\ ab)^2 + \text{rise}^2}{2 \times \text{rise}}$, Figs. 1 and 2.

$= \frac{db^2 §}{2 \times \text{rise}}$, Figs. 1 and 2.

$= \frac{\frac{1}{2}\ ab}{\text{sine of } \frac{1}{2}\ acb}$, Figs. 1 and 2. $= \frac{\frac{1}{2}\ db§}{\text{sine of } \frac{1}{2}\ bcd‖}$, Figs. 1 and 2.

$= \frac{\text{rise } de}{1 - \text{cosine of } \frac{1}{2}\ acb}$, Fig. 1. $= \frac{\text{rise } de}{1 + \text{cosine of } \frac{1}{2}\ acb†}$, Fig. 2.

Rise, or middle ordinate, de,

$= \text{radius} - \sqrt{\text{radius}^2 - (\frac{1}{2}\ ab)^2}$, Fig. 1.

$= \text{radius} + \sqrt{\text{radius}^2 - (\frac{1}{2}\ ab)^2}$, Fig. 2.

$= \text{radius} \times (1 - \text{cosine of } bcd‖)$, Fig. 1.

$= \text{radius} \times (1 + \text{cosine of } bcd‖)$,† Fig. 2.

$= \frac{db^2 §}{2 \times \text{radius}}$, Figs. 1 and 2.

$= \frac{1}{2}\ ab \times \text{tangent of } abd$,* Figs. 1 and 2.

$= \text{approximately } \frac{(\frac{1}{2}\ ab)^2}{2 \times \text{radius}}$, Fig 1.

When radius = chord ab, the result is 6.7 parts in 100 too short.
" " = 3 × chord ab, the result is 0.7 parts in 100 too short.

Side ordinate, as ni,

$= \sqrt{\text{radius}^2 - en^2} + \text{rise} - \text{radius}$, Figs. 1 and 2.

$= \text{approximately } \frac{an \times nb}{2 \times \text{radius}}$. Fig. 1.¶

* abd is = ¼ of the angle acb, subtended by the *arc*.

† Strictly, this should read 1 *minus* cosine; but the cosines of angles between 90° and 270° must then be regarded as *minus* or *negative*. Our rule, therefore, amounts to the same thing.

§ db = chord of dib, or of half adb, $= \sqrt{\text{rise}^2 + (\frac{1}{2}\ ab)^2}$. Figs. 1 and 2.

‖ bcd = half the angle acb subtended by the *arc*. In Fig. 2, the latter angle exceeds 180°.

¶ When radius = chord ab, this makes de 6.7 parts in 100 too short.
" " = 3 × chord ab, this makes de 0.7 parts in 100 too short.
The proportionate error is greater with the side ordinates.

Angle, $a\ c\ b$, subtended by arc, $a\ d\ b$.

Caution. The following sines, etc., are those of only *half* $a\ c\ b$.

Sine of $\frac{1}{2}\ a\ c\ b = \frac{\frac{1}{2}\ a\ b}{\text{radius}}$, Figs. 1 and 2.

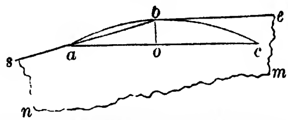
Cosine of $\frac{1}{2}\ a\ c\ b = \frac{\text{radius} - \text{rise}}{\text{radius}}$, Fig. 1; $= \frac{\text{rise} - \text{radius}}{\text{radius}}$, Fig. 2.

Tangent of $\frac{1}{2}\ a\ c\ b = \frac{\frac{1}{2}\ a\ b}{\text{radius} - \text{rise}}$, Fig. 1; $= \frac{\frac{1}{2}\ a\ b}{\text{rise} - \text{radius}}$, Fig. 2.

Versed sine of $\frac{1}{2}\ a\ c\ b = \frac{\text{rise}}{\text{radius}}$, Figs. 1 and 2.

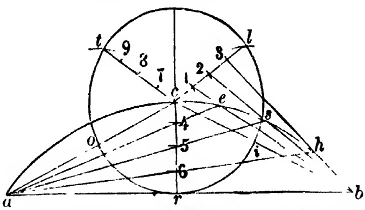
To describe the arc of a circle too large for the dividers.

1st Method. Let $a\ c$ be the chord, and $o\ b$ the height, of the required arc, as



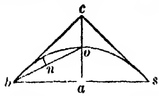
laid down *on the drawing.* On a separate strip of paper, $s\ e\ m\ n$, draw $a\ c$. $o\ b$. and $a\ b$ also $b\ e$, parallel to the chord $a\ c$. It is well to make $b\ s$ and $b\ e$, each a little longer than $a\ b$. Then cut off the paper carefully along the lines $s\ b$ and $b\ e$, so as to leave remaining only the strip $s\ a\ b\ e\ m\ n$. Now, if the straight sides $s\ b$ and $b\ e$ be applied to the drawing, so that any parts of them shall touch at the same time the points a and b, or b and c, the point b on the strip will be in the circumference of the arc, and may be pricked off. Thus, any number of points in the arc may be found, and afterward united to form the curve.

2d Method. Draw the span $a\ b$; the rise $r\ c$; and $a\ c$, $b\ c$. From c with radius



$c\ r$ describe a circle. Make each of the arcs $o\ t$ and $i\ l$ equal to $r\ o$ or $r\ i$; and draw $c\ t$, $c\ l$. Divide $c\ t$, $c\ l$, $c\ r$, each into half as many equal parts as the curve is to be divided into. Draw the lines $b\ 1$, $b\ 2$, $b\ 3$; and $a\ 4$, $a\ 5$, $a\ 6$, extended to meet the first ones at e, s, h. Then e, s, h, are points in one half the curve. Then for the other half, draw similar lines from a to 7, 8, 9; and others from b to meet them, as before. Trace the curve by hand.

Remark.—It may frequently be of use to remember, that in any arc *b o s*, not



exceeding 29°, or in other words, *whose chord bs is at least sixteen times its rise*, the **middle ordinate** *a o*, will be one-half of *a c*, quite near enough for many purposes; *b c* and *s c* being tangents to the arc.† And vice versa, if in such an arc we make *o c* equal *a o*, then will *c* be, very nearly, the point at which tangents from the ends of the arc will meet. Also the **middle ordinate** *n*, **of the half arc** *o b*, or *os*, will be approximately ¼ of *a o*, the middle ordinate of the whole arc. Indeed, this last observation will apply near enough for many approximate uses even if the arc be as great as 45°; for if in that case we take ¼ of *o a* for the ordinate *n*, *n* will then be but 1 part in 104 too small; and therefore the principle may often be used in drawings, for finding points in a curve of too great radius to be drawn by the dividers; for in the same manner, ¼ of *n* will be the middle ordinate for the arc *n b* or *n o*; and so on to any extent. Below will be found **a table by which the rise or middle ordinate of a half arc** can be obtained with greater accuracy when required for more exact drawings.

CIRCULAR ARCS IN FREQUENT USE.

The fifth column is of use for finding points for drawing arcs too large for the beam-compass, on the principle given above. In even the largest office drawings it will not be necessary to use more than the first three decimals of the fifth column; and after the arc is subdivided into parts smaller than about 35° each, the first two decimals .25 will generally suffice. Original.

If the arc, A, is greater than a semicircle, let H = its hight, a = circumf of circle — A, and h = hight of arc, a, = (half-chord)^2 ÷ H. Find a, by table, as above. Then A = circumf — a.

Rectification of Circular Arc.*

(a) Fig. A. **To find approximately* the length of an arc,** $G\ B\ C$. From one end, C, of the arc, draw a tangent, $C\ E$, to the arc (See p 162). Produce the chord, $G\ F\ C$, to D, and make $C\ D = F\ C = \frac{1}{2}\ G\ F\ C$. From D, with radius = $D\ G$, draw the arc $G\ E$. Then $C\ E$ = arc $C\ B\ G$, approximately.*

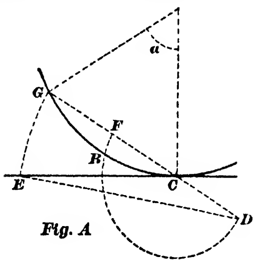

Fig. A

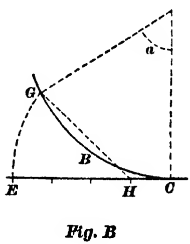

Fig. B

(b) Fig B. On a given circle, **to find an arc,** $G\ C$, approximately* **equal to a given straight line.** $C\ E$. From a point, C, on the circle, draw $C\ E$, tangent, of the given length. Make $C\ H = \frac{1}{4}\ C\ E$. From H, with radius = $H\ E$, draw arc $E\ G$. Then arc $C\ B\ G = C\ E$ approximately.*

(c). On a given circle, **to lay off an arc equal in length to a given arc** on another circle: first, by (a) find a straight line equal to the given arc; then, by (b) lay off the required arc equal to the line so found

* Prof. W. J. M. Rankine, Philosophical Mag., Vol. 34, Oct. and Nov., 1867 The error increases with the fourth power of the angle; but, in an arc of 60 degrees, the error is only about 4 minutes.

LENGTHS OF CIRCULAR ARCS TO RADIUS 1

= Arcs in radians. See p. 97, ¶ 2.

Deg.	Length	Deg.	Length	Min	Length.	Sec.	Length.

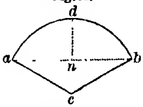
CIRCULAR SECTORS, RINGS, SEGMENTS, ETC.

Fig. A.

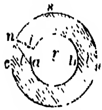


Area of a circular sector, $a\ d\ b\ c$, **Fig. A,**

$= \frac{\text{arc } a\,d\,b}{2} \times \text{radius } c\,a.$

$= \text{area of entire circle} \times \frac{\text{arc } a\,d\,b \text{ in degrees.}}{360}$

Fig. B.



Area of a circular ring, Fig. B,

= area of larger circle, $c\ d$, — area of smaller one, $a\ b$.

= .7854 $\times$ (sum of diams. $c\,d + a\,b$) $\times$ (diff. of diams. $c\,d - a\,b$.)

= 1.5708 $\times$ thickness $c\,a$ $\times$ sum of diameters $c\ d$ and $a\ b$.

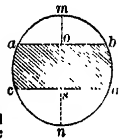
To find the radius of a circle which shall have the same area as a given circular ring $c\ s\ d\ a\ b$, Fig. B,

Draw any radius $n\ r$ of the outer circle; and from where said radius cuts the inner circle at t, draw $t\ s$ at right angles to it. Then will $t\ s$ be the required radius.

Breadth, $c\ a = b\ d$, **of a circular ring,** Fig. B,

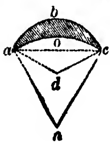
= ½ difference of diameters $c\ d$ and $a\ b$.

= ½ (diameter $c\ d - \sqrt{1.2732 \text{ area of circle } a\,b}$.)



Area of a circular zone $a\ b\ c\ d$,

= area of circle $m\ n$—areas of segments $a\,m\,b$ and $c\,n\,d$,
(for areas of segments, see below.)



A circular lune is a crescent-shaped figure, comprised between two arcs $a\,b\,c$ and $a\,o\,c$ of circles of different radii, $a\ d$ and $a\ n$.

Area of a circular lune $a\ b\ c\ o$

= area of segment $a\ b\ c$ — area of segment $a\ o\ c$,
(for areas of segments see below.)

Circular Segments.

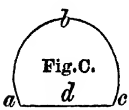


Fig. D.

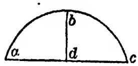

Area of Segment $a\ d\ b\ n$, Fig. A (at top of page)
= Area of Sector $a\ d\ b\ c$ — Area of Triangle $a\ b\ c$.
= ½ (Arc $a\ d\ b$ $\times$ radius $a\ c$ — $c\ n$ $\times$ chord $a\ b$).

Table of Circular Segments, p 187. D = diam of circle.

Rise of seg = R D. **Area of seg** = D^2 A. **If the seg exceeds a semicircle,**

Area = area of circle — area of seg whose rise = (D — rise of given seg.)

For chord, etc. see pp 179–180.

Table of Areas of Circular Segments, Figs C, D, p 186.
D = diam of circle; **R** = Rise / D; **A** = Area / D^2.

THE ELLIPSE

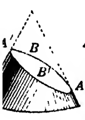

Fig. 1

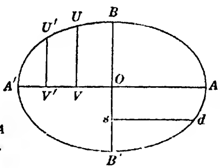

Fig. 2

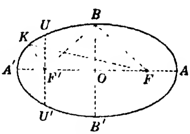

Fig. 3

The ellipse, Fig 1, *A B A' B'*, is the curve formed by the inter-
:tion of a plane with the curved surface of a cone or cylinder
ru which it passes completely and without cutting its base. The
me, "ellipse", is applied also to the plane *figure* enclosed by said
rve, which curve is then called the circumference or periphery of
e ellipse. When the cutting plane is perpendicular to the axis

of the solid ($e = 0$), the ellipse is a circle. When the plane touches the side of the solid ($e = 1$), the ellipse is a straight line.

A diameter, Figs 2 and 3, is any chord passing thru the center, O. Each diam is bisected at the center. An axis, $A A'$ or $B B'$, is a diam dividing the figure symmetrically. The major axis passes thru the foci, F, F', Fig 3. The vertices, A, A', B, B', are the extremities of the axes.

Figs 2-4.	O	=	the center of the ellipse;
	a	=	$O A$ = $O A'$ = the major or transverse semi-axis;
	b	=	$O B$ = $O B'$ = the minor or conjugate semi-axis;
Fig 2.	y, y'	=	$V U, V' U'$ = the ordinate over a point, V, V', in an axis;
	x	=	$O V$ = the distance of y from the center, O;
	x'	=	$A' V$ = $a - x$ = dist of y from the vertex, A';
Fig 3.	F, F'	=	the foci of the ellipse;
	c	=	$O F$ = $O F'$ = $a e$
		=	dist from center, O, to either focus;
	$2 c$	=	$F F'$ = the focal distance;
	e	=	c/a = $\sqrt{(a^2 - b^2)/a^2}$ = the eccentricity;
	Y	=	$F'U$ = the ordinate over either focus;
	p	=	$U U' = 2 Y$ = parameter or latus rectum;
	L	=	$A B A'B'A$ = the circumference or periphery;
Fig 4	r, r'	=	focal radii or radius vectors = dists, $F G$, $F'G$; or $F K$, $F'K$;
	θ, θ'	=	the angles, $G F A'$, $G F'A$; or $K F A'$, $KF'A$;
	S	=	the area of the ellipse;

Equations. Fig 2

(a) Origin of co-ordinates at cen, O : $x = O V$; $y = V U$.

$$(x^2/a^2) + (y^2/b^2) = 1; \text{ whence}$$

$$x = \pm (a/b) \sqrt{b^2 - y^2}; \quad y = \pm (b/a) \sqrt{a^2 - x^2} \quad \ldots\ldots (1)$$

$$y^2 = (a + x)(a - x) b^2/a^2 \quad \ldots\ldots (2)$$

(b) Origin taken at a vertex, A', of major axis, $A A'$; $x' = A'V$.

Here, in Eq 1, $x = a - x'$; $y = \pm (b/a) \sqrt{2ax' - x'^2}$

$$x' = a - x = a + (a/b) \sqrt{b^2 - y^2} \quad \ldots\ldots (3)$$

Ordinates. $VU^2 : AV.VA' = b^2 : a^2$;

$$VU^2 : V'U'^2 = AV.VA' : AV'.V'A' \quad \ldots\ldots (4)$$

Foci. Fig 4. The normal, $P X$, to a tangent, $T T$, thru any point, K, in an ellipse, bisects the angle, FKF', betw the focal radii, KF and KF', of the point K. Hence, a ray (as of light), emitted from either focus, is reflected back to the other. The bisectors, PX, give the positions of the **joints in an elliptic arch,** and enable us **to draw a tangent,** TT, (at right-angles to the bisector) at any point in the ellipse.

Fig 3 Let K and B be any two points in the ellipse. Then $KF + KF' = BF + BF' =$ major axis, $A A' = 2 a$ ..(5)

Or, the ellipse is the locus of a point, the sum of whose distances from two fixt points is constant and equal to the major axis.

Hence, **to locate the foci;** from either end, as B, of the minor axis, lay off BF and BF', each $= a$, to the major axis, AA'.

To draw an ellipse, Fig 4, having AA' and BB'; (a) Place a pin in each focus, located as above. Prepare a string, FKF' or FGF', with a loop at each end (length of string, from end to end of loops, $= 2 a$), and place a loop over each pin. Then a pencil, beginning as at K, and keeping the string constantly and equally stretched, will describe the ellipse, $K G B A B'A'K$. But the string may stretch unequally. Hence :—

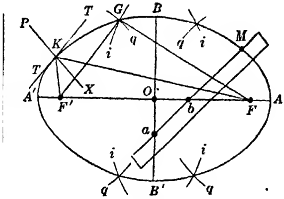

Fig. 4

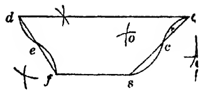

Fig. 7

(b) On a graduated straight-edge, M-a, take M-a = a, and M-b = b. Then, in whatever position the straight-edge is placed, keeping b on AA', and a on BB', M will be in the ellipse.

The ellipsograph (elliptic compasses) employs this principle.

(c) From F and from F', with any radius, R, less than AF', describe four short arcs, $q\ q\ q\ q$; and, with rad $= 2a - R$, four other arcs, $i\ i\ i\ i$. The intersections of these pairs of arcs are points in the ellipse. Find other such points by choosing other radii.

Eccentricity, $e = c/a = \sqrt{(a^2 - b^2)/a^2}$ ....(6)

Polar equation:— $r = \dfrac{a\,(1 - e^2)}{1 - e\cos\theta}$; $r' = \dfrac{a\,(1 - e^2)}{1 - e\cos\theta'}$.(7)

The directrix, EC, is a line such that, for any point, G, in the ellipse, distant g from EC, and with focal radius $r' = F'G$, we have $r'/g = e$. ....(8)

Parameter. Fig 3. For the ordinate, $Y = F'U$, over a focus, F', we have $x^2 = OF'^2 = F'B^2 - OB^2 = a^2 - b^2$; and (eq 1):—
$Y = b^2/a$ ....(9)

Parameter, $UU' = 2Y = 2b^2/a = 2de = 2a(1 - e^2)$ ..(10)
where d = distance from focus to directrix.

Periphery or Circumference. Let $(e^2)/4$ = "II";
$(3e^2/16) \times$ II = "III"; $(15e^2/36) \times$ III = "IV";
$(35e^2/64) \times$ IV = "V", etc. Then —
$L = 2\pi a$ (unity − II − III − IV − V − etc)......(11)
where (− II)/unity $= (-e^2/4)/(+1) = (-\tfrac{1}{4})e^2$;
(− III)/(− II) $= (+\,^3/_{16})e^2$; etc.

Note that, in any given ellipse, e^2 is constant, and that, in the fractions, $(-\,^1/_4)$, $^3/_{16}$, $^{15}/_{36}$, $^{35}/_{64}$, etc, we have:—

Numerators,	(35 − 15) − (15 − 3)	= (15 − 3) − (3 − −1) = 8
Denominators,	(64 − 36) − (36 − 16)	= (36 − 16) − (16 − 4)
		= (16 − 4) − (4 − 0) = 8
Denom − Num,	(64 − 35) − (36 − 15)	= (36 − 15) − (16 − 3)
		= (16 − 3) − (4 − −1) = 8

Or, eq (11) may be written thus:—
$L = 2\pi a\,(1 - Ae^2 - Be^4 - Ce^6 - De^8 - \text{etc})$ .....(12)

Where $A = \dfrac{1}{1}\left(\dfrac{1}{2}\right)^2 = \dfrac{1}{4}$; $C = \dfrac{1}{5}\left(\dfrac{1 \times 3 \times 5}{2 \times 4 \times 6}\right)^2 = \dfrac{5}{256}$;

$B = \dfrac{1}{3}\left(\dfrac{1 \times 3}{2 \times 4}\right)^2 = \dfrac{3}{64}$; $D = \dfrac{1}{7}\left(\dfrac{1 \times 3 \times 5 \times 7}{2 \times 4 \times 6 \times 8}\right)^2 = \dfrac{175}{16384}$.

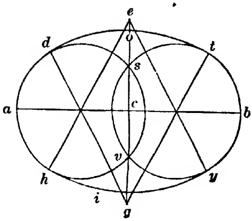

Fig. 5

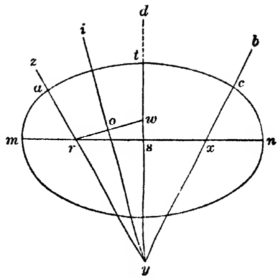

Fig. 6

Approximately :—(from Sir Thomas Muir, F R. S.)

$$L = \frac{\pi}{8}\left(21 \frac{a+b}{2} - 2\sqrt{ab} - \frac{6ab}{a+b}\right) \dots\dots\dots\dots (13)$$

For an ellipse where $a = 10$ and $b = 5$,
eq (11) gives $L = 48.4422$ after deducting term "XXIV";
eq (13) gives $L = 48.4426 = 1.000008 \times 48.4422$

Area of ellipse,

$S = \sqrt{\pi a^2 . \pi b^2} = \pi a b$
$= \pi a^2 (b/a) =$ (area of circle of rad a) $\times$ (b/a) ..(14)

Radius, R, of circle whose area = area, S, of ellipse,
$R = \sqrt{ab}$ ....(15)

Area, Ss, of an elliptic segment whose base is parallel to either axis Divide height of segment by that axis of which said height is a part. Find the quotient under R, in the table of *circular* segments, pp 187-8, and take out the corresponding A. Then
$Ss = 2a \times 2b \times A = 4abA$ ....(16)

The area of an elliptic segment included between two chords, each parallel to either axis, is the diff betw the areas of two segments, each found as above.

To draw an oval, or false ellipse. Fig 5. When only the long diam, *ab*, is given, and when span must not exceed about 3 × *co*. On *ab*, with any radius, *R*, describe two equal intersecting circles. Thru their intersections, *s* and *v*, draw *eg*. Make *sg* = *ve* = 2 *R*. Thru the cens of the circles draw *cy*, *ch*, *gd* and *gt*. From *c*, describe arc *hiy*; and, from *g*, describe *dot*.

Fig 6. When the span, *mn*, and the rise, *st*, are given. Lay off any *tw* and *mr*, equal and each less than *st*. Draw and bisect *rw*, and, thru its cen, *o*, draw the perpendicular, *yoi*. Draw *yrz*. Make *nx* = *mr*, and draw *yxb*. From *x* and from *r*, describe the arcs, *nc* and *ma*; and from *y* describe the arc *atc*. Making *sd* = *sy*, we find the cen, *d*, for the other half of the oval. The shape of the curve depends upon what portion of *st* is taken for *mr* and *tw*. Very flat ovals require more than four cens; and the finding of these cens is quite as troublesome as drawing a true ellipse.

Fig 7. On a given line, *as* or *df*, **to draw a "cyma" or "ogee"**, *acs* or *def*. The cyma recta, *acs*, is concave above; the cyma reversa, *def*, is concave below.

Bisect *as* in *c*. From *a*, *c* and *s*, with radius = $(as)/2$ = *ac* = *cs*, draw the four small arcs at *o* and *o*. The intersections, *o* and *o*, are the cens for drawing the cyma, with the same radius. For *def*, rad = $(df)/2$ = *de* = *cf*.

THE PARABOLA.

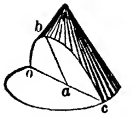

Fig. 1.

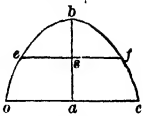

Fig. 2.

The common or conic parabola,

o b c, Fig 1, is a curve formed by cutting a cone in a direction *b a*, parallel to its side. The curved line *o b c* itself is called the *perimeter* of the parabola; the line *o c* is called its *base*; *b a* its height or *axis*; *b* its *apex* or *vertex*; any line *e s*, or *o a*, Fig 2, drawn from the curve, to, and at right angles to, the axis, is an *ordinate*; and the part *s b*, or *a b*, of the axis, between the ordinate and the apex *b*, is an *abscissa*. The *focus* of a parabola is that point in the axis, where the abscissa *b s*, is equal to one-half of the ord *e s*. The dist from apex to focus, called the *focal dist*, is found thus square any ord, as *o a*; div this square by the abscissa *b a* of that ord; div the quot by 4. The nature of the parabola is such that its abscissas, as *b s*, *b a*, &c, are to each other as, or in proportion to, the squares of their respective ords *e s*, *o a*, &c; that is, as $b\,s : b\,a :: e\,s^2 : o\,a^2$; or $b\,s : e\,s^2 \;\; b\,a : o\,a^2$. If the square of any ord be divided by its abscissa, the quot will be a constant quantity; that is, it will be equal to the square of any other ord divided by its abscissa. This quot or constant quantity is also equal to a certain quantity called the *parameter* of the parabola. Therefore the parameter may be found by squaring *e s*, or *o a*, (one-*half* of the base,) and dividing said square by the height *b s*, or *b a*, as the case may be If the square of any ord be divided by the parameter, the quot will be the abscissa of that ord

To find the length of a parabolic curve.

The approximate rule given by various pocket-books, is as follows·

$$\text{Length} = 2 \times \sqrt{(\tfrac{1}{2}\text{ base})^2 + 1\tfrac{1}{3}\text{ times the }(\text{Height}^2)}$$

Where the height does not exceed 1-10th of the base, this rule may, for practical purposes, be called exact. With ht = ¼ base, it gives about ⅙ per cent too much; ht = ½ base, about 3⅓ per cent; ht = base, about 8⅓ per cent; ht = twice the base, about 12⅙ per cent; ht = 10 × base, or more, about 15⅙ per cent

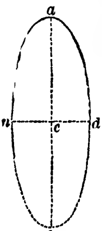

Fig. 4.

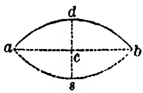

Fig. 3.

The following by the writer is correct within perhaps 1 part in 800 in all cases; and will therefore answer for many purposes.

Let *a d b*, Fig 3, or *n a d*, Fig 4, be the parabola, in which are given the base *a b* or *n d*; and the height *c d* or *c a*. Imagine the complete fig *a d b s*, or *n a d b*, to be drawn; and in *either* case, assume its *long* diam *a b* to be the chord or base, and one-half the short diam, or *c d*, to be the height, of a circular arc Find the length of this circular arc, by means of the rule and table given for that purpose. Then div the chord or base *a b*, or *n d* of the parabola, by its height *c d* or *c a* Look for the quot in the column of bases in the following table, and take from the table the corresponding multiplier. Mult the length of the circular arc by this; the prod will be the length of arc *a d b*, or *n a d*, as the case may be For bases of parabolas less than 05 of the height, or greater than 10 times the height, the multiplier is 1, and is very approximate; or in other words, the parabola will be of almost exactly the same length as the circular arc.

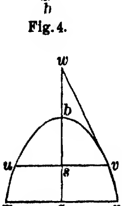

Fig. 5.

To find the area of a parabola *m a n b*.

Mult its base *m n*, Fig 5, by its height *a b*; and take ⅔ds of the prod The area of any segment, as *u b v*, whose base *u v* is parallel to *m n*, is found in the same way, using *u v* and *s b*, instead of *m n* and *a b*.

To find the area of a parabolic zone, or frustum, as *m n u v*.

RULE 1. First find by the preceding rule the area of the whole parabola *m b n*; then that of the segment *u b v*; and subtract the last from the first.

RULE 2. From the cube of *m n*, take the cube of *u v*; call the diff *c*. From the square of *m n*, take the square of *u v*; call the diff *s*. Div *c* by *s*. Mult the quot by ⅔ds of the height *a s*.

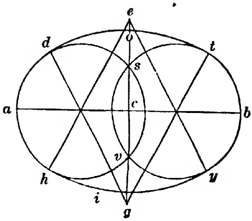

Fig. 5

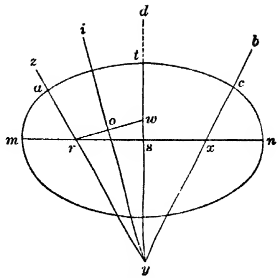

Fig. 6

Approximately :—(from Sir Thomas Muir, F R. S.)

$$L \quad = \quad \frac{\pi}{8} \left(21 \; \frac{a + b}{2} \; - \; 2 \; \sqrt{a\,b} \; - \; \frac{6\,a\,b}{a + b} \right) \ldots\ldots\ldots\ldots (13)$$

For an ellipse where $a \; = \; 10$ and $b \; = \; 5$,
eq (11) gives $L \; = \; 48.4422$ after deducting term "XXIV";
eq (13) gives $L \; = \; 48.4426 \; = \; 1.000008 \times 48.4422$

Area of ellipse,

$S \; = \; \sqrt{\pi\,a^2.\;\pi\,b^2} \; = \; \pi\,a\,b$
$\; = \; \pi\,a^2\,(b/a) \; = \;$ (area of circle of rad a) $\times$ (b/a) ..(14)

Radius, R, of circle whose area = area, S, of ellipse,
$R \; = \; \sqrt{a\,b}$ ....(15)

Area, Ss, of an elliptic segment whose base is parallel to either axis Divide height of segment by that axis of which said height is a part. Find the quotient under R, in the table of *circular* segments, pp 187-8, and take out the corresponding A. Then
$Ss \; = \; 2a \times 2b \times A \; = \; 4\,a\,b\,A$ ....(16)

The area of an elliptic segment included between two chords, each parallel to either axis, is the diff betw the areas of two segments, each found as above.

To draw an oval, or false ellipse. Fig 5. When only the long diam, *ab*, is given, and when span must not exceed about 3 $\times$ *co*. On *ab*, with any radius, R, describe two equal intersecting circles. Thru their intersections, *s* and *v*, draw *eg*. Make $sg = ve = 2\,R$. Thru the cens of the circles draw *cy*, *ch*, *gd* and *gt*. From *c*, describe arc *hiy*; and, from *g*, describe *dot*.

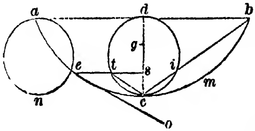
Fig 6. When the span, *mn*, and the rise, *st*, are given. Lay off any *tw* and *mr*, equal and each less than *st*. Draw and bisect *rw*, and, thru its cen, *o*, draw the perpendicular, *yot*. Draw *yrz*. Make $nx = mr$, and draw *yxb*. From *x* and from *r*, describe the arcs, *nc* and *ma*; and from *y* describe the arc *atc*. Making $sd = sy$, we find the cen, *d*, for the other half of the oval. The shape of the curve depends upon what portion of *st* is taken for *mr* and *tw*. Very flat ovals require more than four cens; and the finding of these cens is quite as troublesome as drawing a true ellipse.

Fig 7. On a given line, *as* or *df*, **to draw a "cyma" or "ogee"**, *acs* or *def*. The cyma recta, *acs*, is concave above; the cyma reversa, *def*, is concave below.

Bisect *as* in *c*. From *a*, *c* and *s*, with radius $= (as)/2 = ac = cs$, draw the four small arcs at *o* and *o*. The intersections, *o* and *o*, are the cens for drawing the cyma, with the same radius. For *def*, rad $= (df)/2 = de = ef$.

The Cycloid,

a c b, is the curve described by a point *a* in the circumference of a circle, *a n*, during one complete revolution of the circle, rolled along a straight line *a b*; which is called the base of the cycloid.



The vertex of the cycloid is at *c*.

Base, *a b*, = circumference of generating circle *a n* = diameter, *c d*, of generating circle $\times \pi = 3.1416cd$.

Axis, or height, $cd = an$.

Length, $acb, = 4\,cd$.

Area, $acbd = 3 \times$ area of generating circle, *a n*
$$= 3\frac{cd^2\pi}{4} = cd^2 \times \tfrac{3}{4}\pi = cd^2 \times 2.3562.$$

Center of gravity of *surface* at *g*. $cg = \frac{7}{12}\,cd$. Center of gravity of *cycloid* (curved line *a c b*) in axis *c d* at a point (as *s*) distant $\frac{1}{3}\,cd$ from *c*.

To draw a tangent, *e o*, from any point *e* in a cycloid; draw *e s* at right angles to the axis *c d*; on *c d* describe the generating circle *d c t*; join *t c*; from *e* draw *e o* parallel to *t c*. The cycloid is the **curve of quickest descent:** so that a body would fall from *b* to *c* along the curve *b m c*, in less time than along the inclined plane *b i c*, or any other line.

SOLIDS.

THE REGULAR BODIES.

A regular body, or regular polyhedron, is one which has all its sides, and its solid angles, respectively similar and equal to each other. There are but five such bodies, as follows:

Name.	Bounded by	Surface (= sum of surfaces of all the faces). Multiply the square of the length of one edge by	Volume. Multiply the cube of the length of one edge by
Tetrahedron	4 equilateral triangles.	1.7320	.1178
Hexahedron or cube	6 squares.	6.	1.
Octahedron	8 equilateral triangles.	3.4641	.4714
Dodecahedron	12 " pentagons.	20.6458	7.6631
Icosahedron	20 " triangles.	8.6602	2.1817

Guldinus' Theorem. To find the **volume of any body** (as the irregular mass *a b c m*, Fig A, or the ring *a b c m*, Fig B), generated by a complete or partial revolution of any figure (as *a b c a*) around one of its sides (as *a c*, Fig A), or around any other axis (as *x y*, Fig B).

Fig. A.

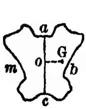


Fig. B.

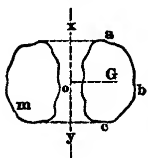

Volume = surface *a b c a* $\times$ length of arc described by its center of gravity G.

If the revolution is complete, the arc described is = circumference = radius $oG^* \times 2\pi$ = radius $oG^* \times 6.283186$; and

Volume = surface *a b c a* $\times$ radius $oG^* \times 6.283186$.

If the revolution is incomplete,
$$\text{complete revolution} : \text{incomplete revolution} :: \text{circumference found as above} : \text{arc described}$$

* Measured perpendicularly to the axis of revolution.

PARALLELOPIPEDS.

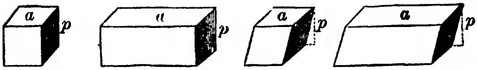

Fig. 1. Fig. 2. Fig. 3. Fig 4.

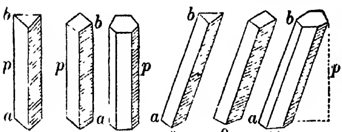
A parallelopiped is any solid contained within six sides, all of which are parallelograms; and those of each opposite pair, parallel to each other. We show but four of them; corresponding to the four parallelograms; namely, the *cube*, Fig 1, which has all its sides equal squares, and all its angles right angles; the *right rectangular prism*, Fig 2, has all its angles right angles, each pair of opposite faces equal, but not all of its faces equal; the *Rhombohedron*, Fig 3, which has all its sides equal rhombuses, and which, like the rhombus, p 157, is sometimes called "rhomb"; the *Rhombic* prism, Fig 4; its faces, rhombuses, or rhomboids, each pair of opposite faces equal, but not all its faces equal. All parallelopipeds are prisms.

Volume of any parallelopiped = area of any face, as a, × *perpendicular* distance, p, to the opposite face.

Volume of a cube = cube of length of one edge,
= 1.909859 × volume of inscribed sphere,
= 1.27324 × " " cylinder,
= 3.81972 × " " cone.

Diagonal of a cube = diameter of circumscribing sphere,
= 1.7320508 × length of one edge of cube.

PRISMS.



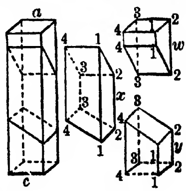
5 6 7 8 9 10

A prism is any solid whose two *ends* are parallel, similar, and equal; and whose *sides are parallelograms*, as Figs 5 to 10. Consequently the foregoing parallelopipeds are prisms. A *right* prism is one whose sides are perpendicular to its ends as 5, 6, 7; when not so, the prism is *oblique*, as 8, 9, 10. When all the sides of the figures which form the ends are equal, and the angles included between those sides are also equal, the prism is said to be *regular*: otherwise, *irregular*.

Volume of any prism (whether regular or irregular, right or oblique)
= area of one end × *perpendicular* distance, p, to the other end,
= area of cross section perpendicular to the sides × actual length, $a\,b$, Figs 5 to 10,
= 3 × volume of pyramid whose base and height are = those of the prism.

To find the volume of any frustum of any prism,

Whose cross section, perpendicular to its sides, is either any triangle; any parallelogram; a square, (as in Fig 10¼) or a *regular* polygon of any number of sides; no matter how the two ends of the frustum may be inclined with regard to each other; or whether one, or neither of them, is parallel to the base of the original prism.



Figs. 10¼.

$$\text{Volume of frustum} = \frac{\text{sum of lengths of } \textit{parallel} \text{ edges, } \overline{1\,1} + \overline{2\,2} + \overline{3\,3} + \overline{4\,4}}{\text{number of such edges (4 in Fig 10¼)}} \times \begin{array}{c}\text{area of cross section}\\ \textit{perpendicular}\\ \text{to such edges.}\end{array}$$

This rule may be used for ascertaining beforehand, the quantity of earth to be removed from a "borrow pit." The irregular surface of the ground is first staked out in squares; (the tape-line being stretched *horizontally*, when measuring off their sides). These squares should be of such a size that without material error each of them may be considered to be a plane surface, either horizontal or inclined. The depth of the horizontal bottom of the pit being determined on, and the levels being taken at every corner of the squares, we are thereby furnished with the lengths of the four parallel vertical edges of each of the resulting frustums of earth. In Figs 10¼, y may be supposed to represent one of these frustums.

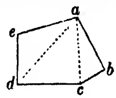


Fig. 10½.

If the frustum is that of an *irregular* 4-sided, or polygonal prism, first divide its cross section perpendicular to its sides, into triangles, by lines drawn from any one of its angles, as *a*, Fig 10½. Calculate the area of each of these triangles separately, then consider the entire frustum to be made up of so many triangular ones; calculate the volume of each of these by the preceding rule for triangular frustums; and add them together, for the volume of the entire frustum.

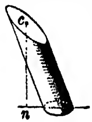

Fig. 10¾.

Volume of any frustum of any prism.

Or of a cylinder. Consider either end to be the base; and find its area. Also find the center of gravity *c* of the other end, and the *perpendicular* distance *n c*, from the base to said center of gravity. Then **Volume of frustum** = area of base × *n c*, Fig 10¾. The slant end, *c*, is an ellipse. Its area is greater than that of the circular end.

Surface of any prism, Figs 5 to 10, whether right or oblique, regular or irregular

$$= \left(\begin{array}{l}\text{circumference measured}\\ \text{perpendicular to the sides}\end{array}\right) \times \text{actual length, } a\,b \Big) + \begin{array}{l}\text{sum of the areas}\\ \text{of the two ends.}\end{array}$$

CYLINDERS.

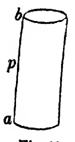

Fig. 11.

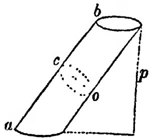

Fig. 12.

A cylinder is any solid whose ends are parallel, similar, and equal *curved* figures; and whose sections parallel to the ends are everywhere the same as the ends. Hence there are circular cylinders, elliptic cylinders (or cylindroids) and many others; but when not otherwise expressed, the circular one is understood. A *right* cylinder is one whose ends are perpendicular to its sides, as Fig 11; when otherwise, it is *oblique*, as Fig 12. If the ends of a right circular cylinder be cut so as to make it oblique, it becomes an elliptic one; because then both its ends, and all sections parallel to them, are ellipses. An oblique circular cylinder seldom occurs; it may be conceived of by imagining the two ends of Fig 12 to be circles, united by straight lines forming its curved sides.

A cylinder is a prism having an infinite number of sides.

Volume of any cylinder (whether circular or elliptic, &c, right or oblique

= area of one end × *perpendicular* distance, *p*, to the other end,

$$= \left\{\begin{array}{l}\text{area of cross section}\\ \text{measured perp to the sides}\end{array}\right. \times \text{actual length, } a\,b\text{, Figs 11 and 12,}$$

= 3 × volume of a cone whose base and height are = those of the cylinder.

Surface of any cylinder (whether circular or elliptic, &c, right or oblique)

$$= \left(\begin{array}{l}\text{circumference}\\ \text{measured perpendicularly}\\ \text{to the sides, as at } c\,o\text{, Fig 12,}\end{array} \times \text{actual length, } a\,b\right) + \begin{array}{l}\text{sum of the areas}\\ \text{of the two ends.}\end{array}$$

Right circular cylinder whose height = diameter.

Volume	= 1½ × volume of inscribed sphere.
Curved surface	= surface of inscribed sphere.
Area of one end	= ¼ surface of inscribed sphere = ¼ curved surface.
Entire surface	= 1½ × surface of inscribed sphere = 1½ × curved surface.

Contents for one foot in length, in Cub Ft, and in U. S. Gallons of 231 cub ins, or 7 4805 Galls to a Cub Ft. **A cub ft of water weighs** about 62½ lbs; and a gallon about 8⅓ lbs **Diams 2, 3, or 10 times as great,** give 4, 9, or 100 times the content.

CONTENTS AND LININGS OF WELLS.

For diams twice as great as those in the table, for the cub yds of digging, take out those opposite *one half* of the greater diam; and mult them by 4. Thus, for the cub yds in each foot of depth of a well 31 feet in diam, first take out from the table those opposite the diam of 15½ feet; namely, 6.989. Then 6.989 × 4 = 27.956 cub yds reqd for the 31 ft diam. But for the stone lining or walling, bricks or plastering, mult the tabular quantity opposite *half* the greater diam, by 2. Thus, the perches of stone walling for each foot of depth of a well of 31 ft diam, will be 2.073 × 2 = 4.146. If the wall is more or less than one foot thick, within usual moderate limits, it will generally be near enough for practice to assume that the number of perches, or of bricks, will increase or decrease in the same proportion.

The size of the bricks is taken at 8¼ × 4 × 2 inches; and to be laid dry, or without mortar. In practice an addition of about 5 per cent should be made for waste. The brick lining is supposed to be 1 brick thick, or 8¼ ins.

CAUTION. — Be careful to observe that the diams to be used for the digging, are greater than those for the walling, bricks, or plastering. No errors.

Diam. in Feet.	For each foot of depth. For this col use the Diameter of the Digging.	For these three cols use the diam in clear of the lining.			Diam. in Feet.	For each foot of depth. For this col use the Diameter of the Digging.	For these three cols use the diam in clear of the lining.

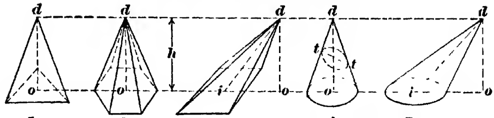
$= \frac{1}{2}$ curved surface of cylinder $xymn$.

PYRAMIDS AND CONES.



1 2 3 4 5

A pyramid, Figs. 1, 2, 3, is any solid which has, for its base, a plane figure of any number of sides, and, for its sides, plane triangles all terminating at one point d, called its *apex*, or top. When the base is a regular figure, the pyramid is *regular;* otherwise *irregular.*

A cone, Figs. 4 and 5, is a solid, of which the base is a curved figure; and which may be considered as made or generated by a line, of which one end is stationary at a certain point d, called the apex or top, while the line is being carried around the circumference of the base, which may be a circle, ellipse, or other curve. A cone may also be regarded as a pyramid with an infinite number of sides.

The axis of a pyramid or cone, is a straight line $d\,o$ in Figs. 1, 2, 4; and $d\,i$ in Figs. 3 and 5, from the apex d, to the center of gravity of the base. When the axis is perpendicular to the base, as in Figs. 1, 2, 4, the solid is said to be a *right* one; when otherwise, as Figs 3, 5, an *oblique* one. When the word cone is used alone, the right circular cone, Fig. 4, is understood. If such a cone be cut, as at $t\,t$, obliquely to its base, the new base $t\,t$ will be an ellipse; and the cone $d\,t\,t$ becomes an oblique elliptic one. Fig. 5 will represent either an oblique circular cone, or an oblique elliptic one, according as its base is a circle or an ellipse.

Volume of pyramid or cone, regular or irregular, right or oblique.

Volume $=$ ⅓ area of base $\times$ *perpendicular* height $d\,o$, or h, Figs 1 to 5.

$=$ ⅓ volume of prism or cylinder having same area of base and same perpendicular height.

$=$ ½ volume of hemisphere of same base and same height.

Or, a cone, hemisphere and cylinder, of the same base and same height, have volumes as 1, 2 and 3.

Area of surface of sides of right regular pyramid or right circular cone.

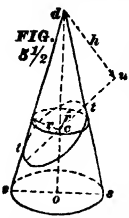
Area $=$ ½ circumference of base $\times$ slant height.*

In the *cone*, this becomes

$$\textbf{Area} = \frac{\text{area of base}}{\text{radius of base}} \times \text{slant height.}$$

Add area of base if required.

FIG. 5½



Area of surface of oblique elliptic cone, $d\,t\,t$, Fig. 5½, cut from a right circular cone, $d\,s\,s$. From the point c where the axis $d\,o$ of the right circular cone cuts the elliptic base $t\,t$, measure a perpendicular, r, in any direction, to the curved surface of the cone. Let v = the volume of oblique elliptic cone, $d\,t\,t$; let a = the area of its elliptic base $t\,t$, and let h = the height $d\,u$ measured perpendicularly to said base. Then

$$\textbf{Curved surface} = \frac{a\,h}{r} = \frac{3\,v}{r}.$$

Add area of base if required

No measurement has been devised for the surface of an **oblique circular cone.**

In an irregular pyramid, right or oblique, **surface area** $=$ sum of areas of sides, each calculated as a triangle, (p 148). Add area of base, if reqd.

* In the *pyramid*, this slant height must be measd along the middle of one of the *sides*, *not* along one of the *edges*.

FRUSTUMS OF PYRAMIDS AND OF CONES.

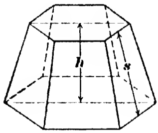


Fig. 6.

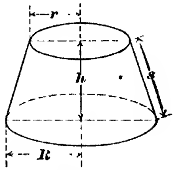

Fig. 7.

In Figs. 6 and 7.

a = area of top; c = circumference of top;
A = " " base; C = " " base;
M = " " section parallel to, and midway between, base and top;
h = height, perp to top and base; s = slant height.*

In Fig. 7.

r = radius of top; R = radius of base.

Volumes.

Frustum of pyramid (Fig. 6) **or of cone** (Fig. 7), regular or irregular, right or oblique, with base and top parallel.

$$\textbf{Volume} = \frac{h}{3}\left(a + A + \sqrt{a\,A}\right) = \frac{h}{6}\left(a + A + 4\,M\right).$$

Frustum of right or oblique circular cone. Fig. 7.

$$\textbf{Volume} = \frac{h}{3}\,\pi\left(r^2 + R^2 + r\,R\right); \quad \pi = 3.1416.$$

Surface area of sides. (Add top and base, if required.)

Frustum of right regular pyramid or cone, top and base parallel, Figs. 6 and 7.

$$\textbf{Area} = \frac{s}{2}\left(c + C\right).*$$

In the right circular conic frustum, this becomes:

$$\textbf{Area} = \pi\,s\,(r + R);* \quad \pi = 3.1416.$$

Frustum of irregular or oblique pyramid:

Area = sum of surfaces of sides.

Each side must be treated as a quadrilateral.
Add areas of top and base, if required.

---

* In the *pyramidal* frustum, Fig. 6, s must be measd along the *middle* of one of the *sides*, as shown, *not* along one of the *edges*.

PRISMOIDS.

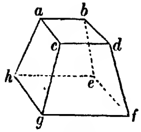

Fig. 1.

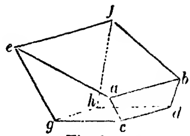

Fig. 2.

A prismoid is sometimes **defined as a solid having** for its ends two parallel plane figures, connected by other plane figures on which, and through every point of which, a straight line may be drawn from one of the two parallel ends to the other. These connecting planes may be parallelograms or not, and parallel to each other or not.

This definition would include the cube and all other parallelopipeds; the prism; the cylinder (considered as a prism having an infinite number of sides); the pyramid and cone (in which one of the two parallel ends, *i e* the one forming the apex, is considered to be infinitely small), and their frustums with top and base parallel; and the wedge.

But the use of the term **prismoid** is frequently **restricted** to six-sided solids, in which the two parallel ends are unequal quadrangles; and the connecting planes, trapezoids; as in Figs. 1 and 2; and, by some writers, to cases where the parallel quadrangular ends are *rectangles.*

The following **"prismoidal formula"** applies to all the foregoing solids, and to others, as noted below.

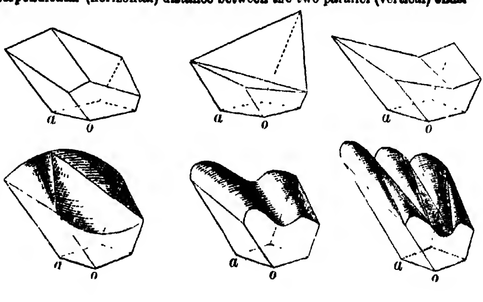
Let A = the area of one of the two parallel ends
a = " " the other of the two parallel ends.
M = " " a cross section midway between, and parallel to, the two parallel ends.
L = the perpendicular distance between the two parallel ends.

Then

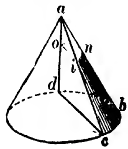
$$\textbf{Volume} = L \times \frac{A + a + 4M}{6}$$

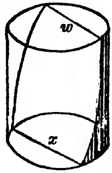
$$= L \times \text{mean area of cross section.}$$

The following six figures represent a few of the irregular solids which fall under the above broad definition of "prismoid," and to which the prismoidal formula applies. They may be regarded as one-chain lengths of railroad cuttings; *a o* being the length, or perpendicular (horizontal) distance between the two parallel (vertical) ends.



The prismoidal formula applies also to the sphere, hemisphere, and other spherical segments; also to any sections such as *a b c d*, and *o n i d b c*, of the





cone, in which the sides *a d*, *a c*, or *o d*, *i c*, are *straight*; as they are only when the cutting plane *a d c* passes *through the apex* or top *a*. **Also to the cylinder** when a plane *parallel to the sides* passes through both ends; but not if the plane *w x* is *oblique*, as in the fig., though never erring more than 1 in 142. **In this last case** we must imagine the plane to be extended until it cuts the side of the cylinder likewise extended; and then by page 199 find the solidity of the ungula thus formed. Then find the solidity of the small ungula above *w*, also thus formed, and subtract it from the large one.

This very extended applicability of the prismoidal formula was first discovered, and made known, by Ellwood Morris, C. E., of Philadelphia, in 1840.

WEDGES.

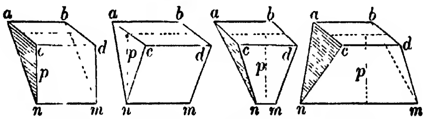


Fig. 8. Fig. 9. Fig. 10. Fig. 11.

A wedge

Is usually defined to be a solid, Figs. 8 and 9, generated by a plane triangle, *a n c*, moving parallel to itself in a straight line. This definition requires that the two triangular ends of the wedge should be parallel; but a wedge may be shaped as in Fig. 10 or 11. We would therefore propose the following definition, which embraces all the figs.; besides various modifications of them. A solid of five plane faces; one of which is a parallelogram *a b c d*, two opposite sides of which, as *a c* and *b d*, are united by means of two triangular faces *a c n*, and *b d m*, to an edge or line *n m*, parallel to the other opposite sides *a b* and *c d*. The parallelogram *a b c d* may be either rectangular, or not; the two triangular faces may be similar, or not; and the same with regard to the other two faces. The following rule applies equally to all:

$$\text{Volume of wedge} = \tfrac{1}{6} \times \begin{array}{c}\text{Sum of lengths}\\ \text{of the 3 edges}\\ ab + cd + nm\end{array} \times \begin{array}{c}\text{perp ht } p \text{ from}\\ \text{edge to back}\end{array} \times \begin{array}{c}\text{width of}\\ \text{back } (a\,b\,c\,d)\\ \text{meas'd perp to } a\,b\end{array}$$

SPHERES OR GLOBES.

A Sphere

Is a solid generated by the revolution of a semicircle around its diameter. Every point in the surface of a sphere is equidistant from a certain point called the center. Any line passing entirely through a sphere, and through its center, is called its *axis*, or diameter. Any circle described on the surface of a sphere, from the center of the sphere as the center of the circle, is called a *great circle* of that sphere, in other words any entire circumference of a sphere is a great circle. A sphere has a greater content or solidity than any other solid with the same amount of surface; so that if the shape of a sphere be any way changed, its content will be reduced. The intersection of a sphere with any plane is a circle.

Volume of sphere

$= \frac{4}{3}\,\pi$ radius^3 $\quad = 4.1888$ radius^3

$= \frac{1}{6}\,\pi$ diameter^3 $\quad = 0.5236$ diameter^3

$= \frac{1}{6}\,\frac{\text{circumference}^3}{\pi^2}$ $\quad = 0.01689$ circumference^3

$= \frac{1}{6}$ diameter $\times$ area of surface

$= \frac{2}{3}$ diameter $\times$ area of great circle

$= \frac{2}{3}$ volume of circumscribing cylinder

$= 0.5236$ volume of circumscribing cube.

Area of surface of sphere

$= 4\,\pi$ radius^2 $\quad = 12.5664$ radius^2

$= \pi$ diameter^2 $\quad = 3.1416$ diameter^2

$= \frac{\text{circumference}^2}{\pi}$ $\quad = 0.3183$ circumference^2

$=$ diameter $\times$ circumference

$= 4 \times$ area of great circle

$=$ area of circle whose diameter is equal to twice diameter of sphere

$=$ curved surface of circumscribing cylinder

$= \frac{6 \times \text{volume}}{\text{diameter.}}$

Radius of sphere

$$= \sqrt[3]{\frac{3}{4}\,\frac{\text{volume}}{\pi}} \quad = 0.62035\,\sqrt[3]{\text{volume}}$$

$$= \sqrt{\frac{\text{Area of surface}}{4\,\pi}} \quad = \sqrt{.07958 \times \text{area of surface}}$$

Circumference of sphere

$$= \sqrt[3]{6\,\pi^2\,\text{volume}} \quad = \sqrt[3]{59.2176\ \text{volume}}$$

$$= \sqrt{\pi\ \text{area of surface}} \quad = \sqrt{3.1416\ \text{area of surface}}$$

$$= \frac{\text{area of surface}}{\text{diameter.}}$$

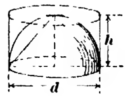
Sphere, S: cone, C: and cylinder, Y: of equal diameters, d, and of equal heights, h ($d = h$).

$$\textbf{Volumes.}\quad Y = \frac{3}{2} S = 3\,C.$$

$$\textbf{Curved Surfaces.}\quad Y = S = \frac{2\,C}{\sqrt{1.25}}.$$



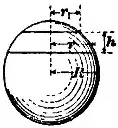
Hemisphere, H: cone, C: and cylinder, Y: of equal diameters, d, and of equal heights, h. ($d = 2\,h$).

$$\textbf{Volumes.}\quad Y = \frac{3}{2} H = 3\,C.$$

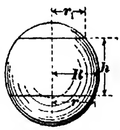
$$\textbf{Curved Surfaces.}\quad Y = H = C\sqrt{2}.$$

Spherical zones and segments.

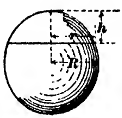
Let R = radius of sphere;
r = radius of base of segment
= radius of either end of zone;
r_1 = radius of other end of zone;
h = height of zone or segment,
$\pi = \frac{\text{circumference}}{\text{diameter}} = 3.14159$.
See p. 161.



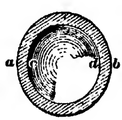
Zone



Zone



Segment



Shell

Then

$$\textbf{Volume of zone} = \frac{\pi}{2}\left(r^2 + r_1^2 + \frac{h^2}{3}\right) h$$

$$\textbf{Volume of segment} = \frac{\pi}{2}\left(r^2 + \frac{h^2}{3}\right) h = \pi\left(R - \frac{h}{3}\right) h^2.$$

$$\textbf{Curved surface of zone or segment} = \frac{h}{2\,R} \times \text{surface of sphere} = \frac{h}{2\,R} \times 4\,\pi\,R^2 = 2\,\pi\,R\,h$$

$$\text{In the segment, } 2\,R = \frac{r^2}{h} + h.$$

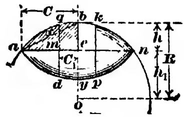
Spherical shell.

Volume = volume of sphere $a\,b$ — volume of sphere $c\,d$

Circular Spindle. Fig, p 209.

The circular spindle is the solid $a\,b\,n\,y\,a$, generated by the revolution of a circular segment, $a\,b\,n\,e\,a$, about its chord, $a\,n$, as an axis. Let

$C = a\,e$ = ½ chord of segment;
$h = e\,b$ = height of segment;
$R = o\,b$ = radius of circle $= \frac{C^2 + h^2}{2\,h}$,
$x = \sqrt{C^2 + h^2}$ = chord of half the segment;
L = length of arc, $a\,b\,n$;
S = area $a\,b\,e = \frac{L\,R}{4} - \frac{C\,h_1}{2}$;
$h_1 = o\,e = R - h$ = distance from cen, o, of circle, to cen, e, of chord.



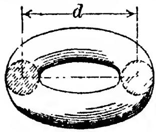
Then, **Volume** $= 4\pi\left(\frac{C^3}{3} - S\,h_1\right)$.

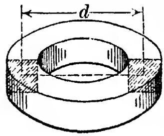
Surface $= 2\pi\,(2C\,R - L\,h_1)$

Middle Zone, $q\,d\,k\,p$; $(C_1 = m\,e.)$

Volume $= 2\pi\left[\left(C^2 - \frac{C_1^2}{3}\right) C_1 - h_1 S_1\right]$, where $S_1 = \frac{\text{area, } q\,d\,k\,p}{2}$.

Circular Ring, of Circular or Rectangular Cross-section.





Let

a = area of cross-section of bar of which ring is made;
c = circumference or periphery of cross-section of bar;
d = half-sum (or average) of inner and outer diameters.

Then,

Volume $= \pi\,a\,d$; **Surface** $= \pi\,c\,d$.

Ellipsoid.

The ellipsoid is the solid generated by the revolution of an ellipse about either axis The generating ellipse may be a variable It revolvs on a constant axis, and its vertices describe either another ellipse or a circle, whose center, in either case, coincides with the center of the generating ellipse, and whose plane is perpendicular to the axis of revolution. See "Spheroid," below.

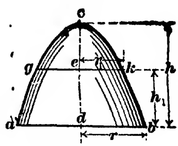
Spheroid.

The spheroid is an ellipsoid in which the generating ellipse is *constant* and in which its vertices describe a *circle*. When the generating ellipse revolvs about its *longer or transverse* axis, the **prolate** spheroid results; when about its *shorter or conjugate* axis, the **oblate** spheroid.

In either case, let f = the *fixt* diam; let m = the *moving* or *revolving* diam, of the ellipse Then: **Volume** $= \pi\,m^2 f/6$ **Surface** (approx) $= \pi\,m\sqrt{(m^2 + f^2)/2}$

The term "ellipsoid" is frequently defined as is "spheroid" above.

Paraboloid.



Paraboloid

The paraboloid is the solid generated by the revolution of a parabola, $a\,c\,b$, about its axis, $c\,d$. r = radius, $d\,b$, of base; h = height, $d\,c$

Volume $= \frac{\pi\,r^2 h}{2} = \frac{h \times \text{area of base}}{2}$;

Curved surface $= \left(\frac{2\,\pi\,r}{12\,h^2}\right)\left[(r^2 + 4h^2)^{\frac{3}{2}} - r^3\right]$

Frustum of paraboloid.

Ends, $g\,k$ and $a\,b$, perpendicular to axis, $d\,c$. r_1 = radius, $e\,k$, of base, $g\,k$. h_1 = height, $d\,e$, of frustum.

Volume = paraboloid, $a\,c\,b$ — paraboloid, $g\,c\,k$, $= \frac{\pi}{2}\,h_1\,(r^2 + r_1^2)$.

Curved surface = surface $a\,c\,b$ — surface $g\,c\,k$.

SPECIFIC GRAVITY.

1. The specific gravity, or relative density, D*, of a substance, is the ratio between the weight, W, of any given volume of that substance and the weight, A, of an equal volume of some substance adopted as a standard of comparison. Or: $D = \frac{W}{A}$.

2. For gaseous substances, **the standard substance** is air, at a temperature of 0° Cent. = 32° Fahr., with barometer at 760 millimeters = 29.922 inches.

3. For solids and liquids, the standard substance is distilled water, at its temperature (4° Cent. = 39.2° Fahr.) of maximum density.

4. For all ordinary purposes of civil engineering, **any clear fresh water, at any ordinary temperature,** may be used. Even with water at 30° Cent., = 86° Fahr., the result is only 4 parts in 1000 too great.

5. When a body is immersed in water, the upward force, or "**buoyancy,**" exerted upon it by the water, or the "**loss of weight**" of the body, due to its immersion, is equal to the weight of the water displaced by the immersion of the body †; or, if

W = the weight of the body in air,
w = its weight in water,
D = its relative density or specific gravity,
A = the weight of water displaced;

then $A = W - w$; and $D = \frac{W}{A} = \frac{W}{W - w}$.

6. Since the volume, V, of a body, of given weight, W, is inversely as its density, or specific gravity, D; the specific gravity is equal also to the ratio between the volume V_s of an equal weight of the standard substance, to the volume, V, of the body in question; or $D = \frac{V_s}{V}$.

7. The specific gravities of **substances heavier than water** are ordinarily determined by weighing a mass of the substance, first in air (obtaining its weight, W), and then when the mass is completely submerged in water (obtaining its diminished weight, w). Then $D = \frac{W}{W - w}$, as in ¶ 5.

8. If the body is lighter than water, it must be entirely immersed, and held down against its tendency to rise. Its weight, w, in water, or its upward tendency, is then a *negative* quantity, and means must be provided for measuring it, as by making it act upward against the scale pan. We then have, $A = W - (-w) = W + w$; or

Loss due to immersion = weight of body in air, *plus* its buoyancy.

9. Or, first allow the body to float upon the water, and note the resulting displacement, v, of water, as by the rise of its surface level in a prismatic vessel. Then immerse the body completely, and again note the displacement, V. Now v, the volume displaced by the body when floating, and V, the volume displaced by the body when completely immersed, are proportional respectively to the weight, W, of the body, and to the weight, $W - w$, of a mass of water of equal volume with the body. Hence $D = \frac{W}{W - w} = \frac{v}{V}$.

10. Or, attach to the light body, b, a heavier body, or sinker, S, of such density and mass that both bodies together will sink in water. Let W be the weight of the light body, b, in air; Q the weight of both bodies in air, and q their combined weight in water. Then $Q - q$ = the weight of a mass of water of equal volume with the two bodies, and $Q - W$ = the weight, S, of the sinker in air. By immersing the sinker alone, find the weight, k, of water equal in volume to the sinker alone, = loss of weight in sinker, due to immersion. Then, for the weight, A, of water of equal volume with the light body, b, or for

---

*Strictly speaking, "specific gravity" refers to *weight*, and "relative density" to *mass* (see Mechanics, Art. 14 *a*); but, as specific gravity and density are numerically equal, they are often treated as identical.

† See Hydrostatics, Art. 18.

the loss of weight of b, due to immersion, we have $A - Q - q - k$; and, for the specific gravity, D, of the light body, b, we have $D = \frac{W}{Q - q - k} = \frac{W}{W - w}$ where w = the (unknown) buoyancy of b.

11. A granular body, as a mass of saw-dust, gravel, sand, cement, etc. or a porous body, as a mass of wood, cinder, concrete, sandstone, etc., is a composite body, consisting partly of solid matter and partly of air. Thus, a cubic foot of quartz sand weighs about 100 lbs., while a cubic foot of quartz weighs about 165 lbs.

12. The specific gravity of porous substances is usually taken as that of the composite mass of solid and air. Thus, a wood, weighing (with its contained air) 62.5 lbs. per cubic foot, or the same as water, is said to have a specific gravity of 1. The absorption of water, when such bodies are immersed for the purpose of determining their specific gravities, may be prevented by a thin coat of varnish.

13. The specific gravity of granular substances is sometimes taken as that of the solid part alone. Thus, Portland cements ordinarily weigh (in air) from 75 to 90 lbs per cubic foot, which would correspond to specific gravities of from 1.20 to 1.44, but the specific gravity of the solid portion ranges from 3.00 to 3.25; and the latter figures are usually taken as representing the specific gravities.

14. In determining the specific gravities of substances (such as cement) which are **soluble in water** or otherwise affected by it, the substances are weighed in some liquid (such as benzine, turpentine or alcohol) which will not affect them, instead of in water. The result, so obtained, must then be multiplied by the ratio between the density of the liquid and that of water.

15. The specific gravity of a liquid is most directly determined by weighing equal volumes of the liquid and of water.

16. Or weigh, in the liquid, some body, whose weight, W, in air, and whose specific gravity, d, are known. Let w' = its weight in the liquid. Then, for the specific gravity, D, of the liquid, we have

$$W : W - w' = d : D; \quad \text{or} \quad D = \frac{d\,(W - w')}{W}.$$

17. Or, let the body, in ¶ 16 (weighing W in air), weigh w in water, and (as before) w' in the liquid in question. Then, since specific gravity of water = 1, we have

$$W - w : W - w' = 1 : D; \quad \text{or} \quad D = \frac{W - w'}{W - w}.$$

18. The specific gravities of liquids are commonly obtained by observing the depth to which some standard instrument (called a **hydrometer**) sinks when allowed to float upon the surface of the liquid. The greater the depth, the less the specific gravity of the liquid. In **Beaumé's hydrometer** the depth of immersion is shown by a scale upon the instrument. The graduations of the scale are arbitrary. For liquids heavier than water, 0° corresponds to a specific gravity of 1, and 76° to a specific gravity of 2 For liquids lighter than water, 10° correspond to a specific gravity of 1, and 60° to a specific gravity of 0.745.

19. In Twaddell's hydrometer, used for liquids heavier than water,

$$\text{specific gravity} = \frac{5 \times \text{No. of degrees} + 1{,}000}{1{,}000}$$

Thus, if the reading be 90°,

$$\text{specific gravity} = \frac{5 \times 90 + 1{,}000}{1{,}000} = \frac{1{,}450}{1{,}000} = 1.45.$$

20. In Nicholson's hydrometer, largely used also for solids, the specific gravity is deduced from the weights required to produce a standard depth of immersion. It consists of a hollow metal float, from which rises a thin but stiff wire carrying a shallow dish, which always remains above water. From the float is suspended a loaded dish, which, like the float, is always submerged. On the wire supporting the upper dish is a standard mark, which, in observations, is always brought to the surface of the water. The specific gravity is then determined by means of the weights carried in the two dishes respectively.

21. The determination of the **specific gravities of gaseous substances** requires the skill of expert chemists.

Table of specific gravities, and weights.

In this table, the sp gr of air, and gases also, are compared with that of water instead of that of air; which last is usual.

The specific gravity of any substance is = **its weight in grams per cubic centimetre.**	Average Sp Gr.	Average Wt of a Cub Ft Lbs.
Air, atmospheric; at 60° Fah, and under the pressure of one atmosphere or 14.7 lbs per sq inch, weighs $\frac{1}{815}$ part as much as water at 60°..........	.00123	0765

† From very careful weighings in the Chicago yards of Coxe Bros. & Co Note the irregular variation with size of anthracite in Coxe Bros.' figures.

§ Quoted from *The Mining Record*. On the authority of "many years' experience" of "a prominent retail dealer in Philadelphia," the Journal gives also figures requiring from 4 to 13 per cent. less volume per ton than those here quoted from the Journal and from other authorities.

WEIGHTS AND MEASURES.

United States and British measures of length and weight, of the same denomination, may, *for all ordinary purposes*, be considered as equal; but the **liquid and dry** measures of the same denomination differ widely in the two countries. **The standard measure of length** of both countries is theoretically that of a pendulum vibrating seconds at the level of the sea, in the latitude of London, in a vacuum, with Fahrenheit's thermometer at 62°. The length of such a pendulum is supposed to be divided into 39.1393 equal parts, called inches; and 36 of these inches were adopted as the standard yard of both countries. But the Parliamentary standard having been destroyed by fire, in 1834, it was found to be impossible to restore it by measurement of a pendulum. The present British Imperial yard, as determined, at a temperature of 62° Fahrenheit, by the standard preserved in the Houses of Parliament, is the standard of the United States Coast and Geodetic Survey, and is recognized as standard throughout the country and by the Departments of the Government, although not so declared by Act of Congress The yard between the 27th and 63d inches of a scale made for the U S Coast Survey by Troughton, of London, in 1814, is found to be of this standard length when at a temperature of 59°.62 Fahrenheit; but at 62° is too long by 0.00083 inch, or about 1 part in 43373, or 1 46 inch per mile, or 0.0277 inch in 100 feet.

The Coast Survey now uses, for purposes of comparison, two measures presented by the British Government in 1855, as copies of the Imperial standard, namely:

"Bronze standard, No 11," of standard length at 62° 25 Fahr.
"Malleable iron standard, No. 57," " " " 62°.10 "

See Appendix No. 12, Report of U. S. Coast and Geodetic Survey for 1877.

The legal standard of weight of the United States is the **Troy pound of the Mint** at Philadelphia. This standard, containing 5760 grains, is an exact copy of the **Imperial Troy pound of Great Britain.** The avoirdupois or commercial pound of the United States, containing 7000 grains, and derived from the standard Troy pound of the Mint, is found to agree within one thousandth of a grain with the British avoirdupois pound. The U. S. Coast Survey therefore declares the weights of the two countries identical.

The Ton. In Revised Statutes of the United States, 2d Edition, 1878, Title XXXIV, Collection of Duties upon Imports, Chapter Six, Appraisal, says:

"Sec 2951. Wherever the word 'ton' is used in this chapter, in reference to weight, it shall be construed as meaning twenty-hundredweight, each hundredweight being one hundred and twelve pounds avoirdupois."

This appears to be the only U. S. Government regulation on the subject.

The ton of 2240 lbs (often called **a gross ton** or **long ton**) is commonly used in buying and selling iron ore, pig iron, steel rails and other manufactured iron and steel. Coke and many other articles are bought and sold by the **net ton** or **short ton** of 2000 lbs. The bloom ton had 2464 lbs, = 2240 lbs + 2 hundredweight of 112 lbs each; and the pig iron ton had 2268 lbs, = 2240 lbs + a "sandage" of 28 lbs, or one "quarter," to allow for sand adhering to the pigs, but some furnace men allowed only 14 lbs. In electric traction work the ton means 2000 lbs.

As a measure, the ton, or tun, is defined as 252 gallons, as 40 cubic feet of round or rough timber or in ship measurement, or as 50 feet of hewn timber. 252 U. S. gallons of water weigh about 2100 lbs; 252 Imperial gallons about 2500 lbs; 50 cub ft yellow pine about 2500 lbs.

The metric system* **was legalized in the United States** in

* The metric system, as compared with the English, has much the same advantages and disadvantages that our American decimal coinage has in comparison with the English monetary system of pounds, shillings and pence. It will enormously facilitate all calculations, but, like all other improvements, it will necessarily cause some inconvenience while the change is being made. The metric system has also this further and very great advantage, that it bids fair to become universal among civilized nations.

1866, but has not been made obligatory. The government has since furnished very exact metric standards to the several States. The use of the metric system has been permitted in Great Britain, beginning with August 6, 1897, and in Russia, beginning with 1900. Its use is now at least permissive in most civilized nations.

The metric unit of length is the metre, or meter, which was intended to be one ten-millionth $\left(\frac{1}{10,000,000}\right)$ of the earth's quadrant, *i. e.*, of that portion of a meridian embraced between either pole and the equator This length was measured, and a set of metrical standards of weight and measure were prepared in accordance with the result, and deposited among the archives of France at Paris (Mètre des Archives. Kilogramme des Archives, etc.) It has since been discovered that errors occurred in the calculations for ascertaining the length of the quadrant; but the standards nevertheless remain as originally prepared

The metric measures of surface and of capacity are the squares and cubes of the meter and of its (decimal) fractions and multiples.

The metric unit of weight is the gramme or gram, which is the weight of a milliliter or cubic centimeter* of pure water at its temperature of maximum density, about 4° Centigrade or 39 2° Fahrenheit.

By the concurrent action of the principal governments of the world, an **International Bureau of Weights and Measures** has been established, with its seat near Paris It has prepared two ingots of pure platinum-iridium, from one of which a number of standard kilograms (1000 grams) have been made, and from the other a number of standard meter bars, both derived from the standards of the Archives of France. Of these copies, certain ones were selected as international standards, and the others were distributed to the different governments. Those sent to the United States are in the keeping of the U. S. Coast Survey.

The determination of the **equivalent of the meter in English measure** is a very difficult matter. The standard *meter* is measured *from end to end* of a *platinum* bar and at the *freezing* point; whereas the standard *yard* is measured *between two lines* drawn on a *silver* scale inlaid in a *bronze* bar, and *at* 62° *Fahrenheit* **The United States Coast Survey**† adopts, as the length of the meter at 62° Fahrenheit, the value determined by Capt. A. R. Clarke and Col. Sir Henry James, at the office of the British Ordnance Survey. In 1866, viz.: 39.370432 inches (= 3 2808666 + feet = 1.0936222 + yards); but the **lawful equivalent,** established by Congress, is 39 37 inches (= 3.28083 feet = 1.093611 yards). This value is as accurate as any that can be deduced from existing data.

The gram weighs, by Prof W. H. Miller's determination,‡ 15.43234874 grains An examination made at the International Bureau of Weights and Measures in 1884 makes it 15.43235639 grains. The **legal value** in the United States is 15.432 grains.

---

* 1 centimeter = $\frac{1}{100}$ meter = 0.3937 inch. 1 milliliter ($\frac{1}{1000}$ liter) or cubic centimeter = 0.061 + cubic inches.

Perfectly pure gold is worth $1 per 23.22 grs = $20.67183 per troy oz = $18 81151 per avoir oz. **Standard** (U S coin) is worth $18 60465 per troy oz = $16.95736 per avoir oz It consists of 9 parts by weight of pure gold, to 1 par alloy Its value is that of the pure gold only; the cost of the alloy and of th coinage being borne by Government **A cubic foot of pure gold weigh** about 1204 avoir lbs; and is worth $362963. A cubic inch weighs about 11.14 avoir oz: and is worth $210.04.

Pure gold is called one, or 24 **carat** gold; and when alloyed, the alloy is sup posed to be divided into 24 parts by weight, and according as 10, 15, or 20, &c o these parts are pure gold, the alloy is said to be 10, 15, or 20, &c, carat.

The average fineness of California native gold, by some thou sands of assays at the U. S. Mint in Philada., is 88.5 parts gold, 11 5 silver. Som from Georgia, 99 per cent gold.

Pure silver fluctuates in value· thus, during 1878–1879 it ranged betwee $1 05 and $1 18 per troy oz, or $.957 and $1.076 per avoir. oz. A cubic inch weigh about 5.528 troy, or 6.065 avoir ounces

* Latin Union (France, Belgium, Italy, Switzerland, Greece). Fineness, gold and 5 franc silver, 0.9; minor silver coins, 0.835.

† Scandinavian Union (Sweden, Norway, Denmark).

Troy Weight. U. S. and British.

24 grains	1 pennyweight, dwt.
20 pennyweights	1 ounce = 480 grains.
12 ounces	1 pound = 240 dwts. = 5760 grains.

Troy weight is used for gold and silver.

A carat of the jewellers, for precious stones is, in the U. S. = 3.2 grs.; in London, 3.17 grs., in Paris, 3.18 grains, divided into 4 jewellers' grs. **In troy, apothecaries' and avoirdupois, the grain is the same.**

Apothecaries' Weight. U. S. and British.

20 grains	1 scruple.
3 scruples	1 dram = 60 grains.
8 drams	1 ounce = 24 scruples = 480 grains
12 ounces	1 pound = 96 drams = 288 scruples = 5760 grains.

In troy and apothecaries' weights, the grain, ounce and pound are the same.

Avoirdupois or Commercial Weight. U. S. and British.

27.34375 grains	1 dram
16 drams	1 ounce = 437½ grains.
16 ounces	1 pound = 256 drams = 7000 grains.
28 pounds	1 quarter = 448 ounces.
4 quarters	1 hundredweight = 112 lbs.
20 hundredweights	1 ton = 80 quarters = 2240 lbs.

A stone = 14 pounds. **A quintal** = 100 pounds avoir.

The standard of the avoirdupois pound, which is the one in common commercial use, is the weight of 27.7015 cub ins of pure distilled water, at its maximum density at about 39°.2 Fahr, in latitude of London, at the level of the sea; barometer at 30 ins. But this involves an error of about 1 part in 1362, for the 1 lb of water = 27.68122 cub ins.

A troy lb = .82286 avoir lb. An avoir lb = 1.21528 troy lb, or apoth.

A troy oz. = 1.09714 avoir oz. An avoir oz = .911458 troy oz, or apoth.

Long Measure. U. S. and British.

12 inches	1 foot = .3047973 metre
3 feet	1 yard = 36 ins = .9143919 metre
5½ yards	1 rod, pole, or perch = 16½ feet = 198 ins.
40 rods	1 furlong = 220 yards = 660 feet
8 furlongs	1 statute, or land mile = 320 rods = 1760 yds = 5280 ft = 63360 ins.
3 miles	1 league = 24 furlongs = 960 rods = 5280 yds = 15840 ft

A point = $\frac{1}{72}$ inch. **A line** = 6 points = $\frac{1}{12}$ inch. **A palm** = 3 ins. **A hand** = 4 ins. **A span** = 9 ins. **A fathom** = 6 feet. **A cable's length** = 120 fathoms = 720 feet. **A Gunter's surveying chain** is 66 feet, or 4 rods long. It has 100 links, 7.92 inches long. 80 Gunter's chains = 1 mile.

A nautical mile, geographical mile, sea mile, or knot, is variously defined as being = the length of

		metres	feet	statute miles
1 min of longitude at the equator	=	1855.345	6087.15	1.15287
1 " latitude " "	=	1842.787	6045.95	1.14507
1 " " " pole	=	1861.655	6107.85	1.15679
1 " " at lat 45°	=	1852.181	6076.76	1.15090
1 " a great circle of a *true* sphere whose *surface area* is equal to that of the earth	=	value adopted by **U. S. Coast and Geodetic Survey** 1853.248	6080.27	1.15157
British **Admiralty knot**	=	1853.169	6080.00	1.15152

Navigators use **"knot"** to mean a *speed* of 1 knot *per hour*.

Minutes, in meters and in ft, as above, calculated from Clarke's spheroid. U. S. Coast & Geod Survey, Rept for 1881, App. 12.

Radius	Arc of 1 Deg	Arc of 1 Min	Arc of 1 Sec
100 ft	1.74533 ft	0.02909 ft	0.000485 ft
1 mile	92.1534 ft	1.5359 ft	0.0256 ft

Earth's great circle. Radius, equatorial, = 3963.27 miles; polar = 3949.83 miles. **Arc of 1°** = chord of 1° + 4.6356 feet.

Length of degree of latitude, in miles. At equator, 68.70; at lat 20°, 68.78; 40°, 69.00; 60°, 69.23; 80°, 69.39; 90°, 69.41.

Lengths of a Degree of Longitude in different Latitudes, and at the level of the Sea. These lengths are in common land or statute miles, of 5280 ft. Since the figure of the earth has never been *precisely* ascertained, these are but close approximations. Intermediate ones may be found correctly by simple proportion. 1° of longitude corresponds to 4 mins of civil or clock time; 1 min of longitude to 4 secs of time.

Square or Land Measure. U. S. and British.

144	square inches	=	1 square foot. (100 sq ft = **1 square**);
9	square feet	=	1 square yard = 1296 square inches;
30.25	square yards	=	1 square rod = 272.25 square feet;
40	square rods	=	1 rood = 1210 square yards;
4	roods	=	1 acre = 160 rods = 4840 sq yds = 43,560 sq ft;
640	acres	=	1 square mile.

U. S. Public Lands are divided into townships, sections and quarter-sections, bounded by meridians and parallels. Nominally a **township** is 6 miles square and contains 36 **sections**, each 1 mile square and containing 4 **quarter-sections**, 0.5 mile square. By law, errors, including those due to **convergence of the meridians**, are shifted to the northern and western quarter-sections of the township.

Dry Measure. U. S. only.

Based upon the old British Winchester struck bushel of 2150.42 cubic inches. Dimensions, 18.5 ins inner diam; 19.5 ins outer diam; 8 ins deep. When heaped, cone not less than 6 ins high.

2 pints = 1 quart	2 gallons = 1 peck = 8 qts = 16 pints
4 quarts = 1 gallon = 8 pints	4 pecks = 1 bushel = 8 gals = 32 qts = 64 pints

Cement barrels, approximate dimensions, etc.

Portland. Height, between heads, 2 to 2.2 ft. Capacity, between heads, 3.1 to 3.5 cu ft. Cement in barrel, net 370 to 387 lbs; packed, 3 to 3.5 cu ft; loose, 3.7 to 4.2 cu ft. Weight per cu ft: packed, 114 to 123 lbs; loose, 89 to 100 lbs.§

Natural. Capacity, 3.4 to 3.8 cu ft. Net weight, Western states, 265 lbs; Eastern states, 300 lbs; making weight per cu ft, packed, 78 to 79 lbs.

Cement bags. Am Soc for Testing Materials¶ specifies, Nov 14, 1904, that a bag shall contain 94 lbs net. Portland, 4 bags to a barrel; natural, 3 bags.

---

* Abbreviation of Latin, Congius. † Abbreviation of Latin, Octarius.

‡ At its maximum density, 62.425 lbs per cub ft, corresponding to a temp of 4° C = 39.2° F.

§ Sanford E. Thompson, Eng. News, Oct. 4, 1900.

¶ Proceedings, 1904, Vol IV, p. 107.

Bushels and Barrels.

A struck bushel = 1.24446 cubic feet;
A cubic foot = 0 80356 struck bushel;
A flour barrel = 3.75 cubic feet = 3 struck bushels.
In ordering by the barrel, specify its contents, as in pounds or in cubic inches.

British Imperial Measure.

Act of Parliament of 1897. Order of Council issued 1898, May 19.

			Logarithm
1 Imperial gallon =	4.545 963 1	liters	0 657 6259

The gramme is the basis of French weights; and is the weight of a cub centimetre of distilled water at its max density, at sea level, in lat of Paris; barom 29.922 ins.

French Measures of the "Systeme Usuel."

This system was in use from about 1812 to 1840, when it was forbidden by law to use even its names. This was done in order to expedite the general use of the tables which we have before given. But as the Systeme Usuel appears in books published during the above interval, we add a table of some of its values.

Measures of Length.

Toise ancien, = 6.3946 ft = 2.1315 yds	....	40 8908	4.5434	......	261 482	9.6845
League = 2282 toises = 2.7637 miles						

There is, however, much confusion about these old measures. Different measures had the same name in different provinces.

* The *avoirdupois* quintal is 100 avoirdupois pounds.

Russian.

Foot; same as U. S. or British foot. **Sachine** = 7 feet. **Verst** = 500 sachine = 3500 feet = 1166⅔ yards = .6629 mile. **Pood** = 36.114 ℔s avoirdupois

Spanish.

The castellano of Spain and New Granada, for weighing gold, is variously estimated, from 71.07 to 71.04 grains. At 71.055 grains, (the mean between the two,) an avoirdupois, or common commercial ounce contains 6.1572 castellano; and a ℔ avoirdupois contains 98.515. Also a troy ounce = 6.7553 castellano; and a troy ℔ = 81.064 castellano. Three U. S. gold dollars weigh about 1.1 castellano.

The Spanish mark, or marco, for precious metals, in South America, may be taken in practice, as .5065 of a ℔ avoirdupois. In Spain, .5076 ℔. In other parts of Europe, it has a great number of values; most of them, however, being between .5 and .54 of a pound avoirdupois. The .5065 of a ℔ = 3545½ grains; and .5076 ℔ = 3553.2 grains. 1 marco = 50 castellanos = 400 tomine = 4800 *Spanish gold*-grains.

The arroba has various values in different parts of Spain. That of Castile or Madrid, is 25.4025 ℔s avoirdupois; **the tonelada** of Castile = 2032.2 ℔s avoirdupois; **the quintal** = 101.61 ℔s avoirdupois; **the libra** = 1.0161 ℔s avoirdupois; **the cantara** of wine, &c, of Castile = 4.263 U. S. gallons; that of Havana = 4.1 gallons.

The vara of Castile = 32.8748 inches, or almost precisely 32⅞ inches; or 2 feet 8⅞ inches. **The fanegada** of land since 1801 = 1.5871 acres = 69134.08 square feet. **The fanega** of corn, &c = 1.59914 U. S. struck bushels. In California, **the vara by law** = 33.372 U. S. inches; and **the legua** = 5000 varas; or 2.6335 U. S. miles.

CONVERSION TABLES OF UNITS OF MEASURES, WEIGHTS, Etc., Etc., Introduction.

In the following tables **repeating decimals** are indicated by a *. Thus: 1.2*01 = 1.2010101 . . . ; 333.*5657 = 333.56575657 . . .

Exact values are indicated by a †. Thus: 1 ft = 12† ins; 1 meter = 0.001† kilometer.

Negative characteristics are indicated by the letter n. Thus: n 1.285 5573 = $\bar{1}$ 285 5573 = 0.285 5573 — 1 = 9.285 5573 — 10. For the use of logarithms, see pp. 70, etc.

Gunter's and Engineers' **chains and links** are distinguished by the letters G and E respectively. Thus: 1 chain G = 66† ft; 1 link E = 1† ft.

Table A contains the equations taken as the basis of Tables 1 to 36 inclusive.

In Table C we give equivalents and numbers in common use, in order to facilitate the transformation of equations, as explained below.

Each table has been calculated independently by at least two persons, and their results compared and corrected. One of these results was used as copy for the compositor, and his proofs were compared with the other.

The calculations comprised many times the number of equations here given. To have published any considerable proportion of those calculated would have made far too bulky a table for an Engineer's Pocket Book. With a little practice, however, the reader can easily find other equations by means of those given. In doing this, the logarithms given in Table C will be found useful.

Thus, suppose we desire the length of the meter, in rods. In Table 1 (Length) or in Table C (Equivalents in Common Use), we find

1 meter = 3.28083 feet,	Log	0.515 9842

and in Table 1 we find

1 foot = 0.*0606 rod,	Log	n 2.782 5161

Adding logs, we find

1 meter = 0.19884 rod,	Log	n 1.298 5003

Again: 1 meter per second = ? miles per day.

Table 18 (Length per Time, or Velocity) gives

1 meter per second = 2.23693 miles per hour.	Log	0.349 6528

and Table 5 (Time) or Table C gives

1 day = 24 hours	Log	1.380 2112

Adding logs, we obtain

1 meter per second = 53.686 miles per day		1.729 8640

Again:

1 cu ft per sq mile per sec = ? U. S. gals per acre per day.

$$1 \text{ cu ft per sq mile per sec} = \frac{1{,}728 \times 86{,}400}{231 \times 640} \text{ gals per acre per day.}$$

Table C gives

	Log	1,728	3.237 5437
Add	Log	86,400	4 936 5137

1 cu ft per acre per sec = x cu ins per acre per sec 8.174 0574

Subtract sum of	Log 231	2.363 6120	
and	Log 640	2 806 1800	5 169 7920

1 cu ft per sq mile per sec = 1009.87 gals per acre per day 3.004 2654

In a few cases, of frequent occurrence, we give two tables, each containing the reciprocals of the values given in the other. Thus, we give Weights of Volumes (as 1 cu ft = ? lbs) and Volumes of Weights (as 1 lb = ? cu ft) of Water; Volume per Surface to Length (as 1 gal per acre = ? ins.) and Length to Volume per Surface (as 1 inch = ? gals per acre), etc., etc. Where only one of two such reciprocal values is given, the other may easily be found from it. Thus, (But see CAUTION, next page.)

	Log 1	0.000 0000
1 ft per sec = 720 ins per minute.	Log	2.857 3325
1 sec per ft = 0 0013*888 min per inch.	Log	n 3.142 6675

* Repeating decimals. † Exact values. n Negative characteristic. E. Engineer's. G. Gunter's.

CONVERSION TABLES, Introduction (Continued).

Caution. It will be noticed that, although a body moving 1 foot per second (or 720 inches per minute) requires 1 sec to travel 1 ft (or 0.0013*888 min to travel 1 inch), and although 1 ft per sec and 1 sec per ft are also *numerically* equal, they are not really identical, but reciprocal. Thus, also,

1 dime per dollar = 1 : 10
but 1 dollar per dime = 10 : 1.

In selecting equations for publication, we have in general given preference to those which cannot easily be found by means of others in the same table, or by means of simpler tables. Thus, having given, in Table 12 (Weight per Surface), the equivalent of 1 kilogram per sq centimeter, in pounds per sq *inch*, we omit the equivalent in pounds per sq *foot*, which is readily found, by using Table 2 (Surface), from the given equivalent in pounds per sq *inch*.

Again, the equivalents of a pressure of 1 pound per sq inch, in ounces per sq inch, and in pounds per sq foot, are not given in Table 12 (Weight per Surface); because they are easily deduced from 1 pound per sq inch, by means of Table 4 (Weight) and Table 2 (Surface), respectively.

The ratios between the values of the coins of different nations being subject to change, the equivalents in Tables 25 to 30 inclusive (Values) can at best be only rudely approximate. Their logarithms are therefore given to only three places of decimals, although the calculations were made by means of seven-place logarithms. Conversions of such approximate equivalents may be conveniently made by means of our two-page table of 4-place logarithms, pp. 78 and 79, omitting the last decimal place. Indeed, the two-page table, which obviates the necessity of turning over pages, may often be used to advantage in dealing with quantities more accurately known.

List of Tables.

* Repeating decimals. † Exact values. n, Negative characteristic. E. Engineer's. G, Gunter's.

CONVERSION TABLES, Introduction (Continued).

Table A.

Fundamental Equivalents.

(*See Notes below.*)

			Logarithm
1 meter =	39 37	inches (a)	1 595 1654
1 gram =	15 43235	grains (a)	1.188 4320
1 cu centimeter water weighs	1	gram (a)	0.000 0000
1 cu meter air weighs	1 293052	kilograms (b)	0.111 6159
1 inch mercury =	13 5956	inches water (c)	1.133 4112
1 atmosphere =	760	mm of mercury	2 880 8136
1 pound Fahr (B. T. U) =	778	foot-pounds (d)	2.890 9796
g = acceleration of gravity =	9 81	meters per second per second (e)	0.991 6690
£ 1 =	$4 86	(f)	0 686 6363
1 franc =	$0.193	(f)	n 1 285 5573
1 mark =	$0.238	(f)	n 1.376 5770

(a) See p 217.
(b) See Density of air, p 320.
(c) 1 inch mercury = 13 5956 inches water. Value adopted by International Bureau of Weights and Measures. Lat. 45°. Sea level. Temperature of mercury 0° C. = 32° Fahr.
(d) 1 pound Fahr = 778 foot-pounds. According to very careful determinations by Prof Henry A. Rowland (Proceedings, Am. Acad. Arts and Sciences for 1880) and generally accepted as standard.
(e) g = 9 81 meters per sec per sec Generally accepted average. At latitude 45° and at sea level, g = 9 806056 m. For other latitudes, L, and elevations h, in centimeters;
g in centimeters per sec per sec = approx 980 6056 — 2.5028 cos 2 L — 0.000003 h.
(f) According to circular of U. S. Treasury Department, Bureau of the Mint, Jan'y 1, 1887, £1 = $4 8665 gold; 1 franc = $0.193; 1 mark = $0 238.

Functions of Grades.

Tables of Grades. pages 255 to 257 See Figs, p. 255.

Rise $= v$; **Slope** $= s$; **horizontal distance** $= h$; $\sin A = v/s$; $\cos A = h/s$; $\tan A = v/h$; $\text{ctn}\ A = h/v$; $\sec A = s/h$; $\csc A = s/v$.

	In small angles, approximately
$v = s\,.\sin A = h\,.\tan A = h \div \text{ctn}\ A = s \div \csc A$	$v = 0.01745\ s\ A°$
$s = v \div \sin A = h \div \cos A = h\,.\sec A = v\,.\csc A$	$s = 57.30\ v \div A°$
$h = s\,.\cos A = v \div \tan A = v\,.\text{ctn}\ A = s \div \sec A$	$h = 57.29\ v \div A°$
In feet per mile, $v \div s = 5280 \sin A$	$v - s = 92.149\ A°$
$v \div h = 5280 \tan A$	$v \div h = 92.163\ A°$

The ratios for an angle of 1° are shown in the three figures opposite, in which the angle is necessarily exaggerated. **In small angles** the rise, in a given distance, may be taken as varying directly, and the sloping and horizontal distances, for a given rise, inversely, as the angle itself, expressed in degrees, as indicated above in the column headed "In small angles." Thus, in clinometer work, with small angles, 57.3 feet $\div A° =$ distance (horizontal or sloping) in feet per foot of rise. Hence, for small angles;

Sloping or horizontal distance, s or h, in feet $= 57.3\ v \div A°$.

Table of grades per mile, and per 100 feet measured horizontally, and corresponding to different angles of inclination.

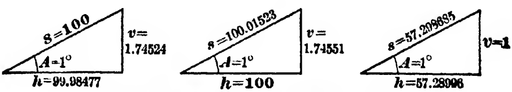
On a turnpike road 1° 38′, or about 1 in 35, or 151 feet per mile, is the greatest slope that will allow horses to trot down rapidly with safety. In crossing mountains, this is often increased to 3°, or even to 5°. It should never exceed 2½°, except when absolutely necessary.

Any hor dist is = sloping dist × cosine ang of slope.
" sloping dist is = hor dist ÷ cosine " " "
" vert height is = hor dist × tangent " " "
or = sloping dist × sine " " "

A grade of n feet rise per 100 feet horizontal is usually called a grade of **n per cent.**



Functions of grade of 1 degree. See p 254.

SLOPES IN FEET PER 100 FT. HORIZONTAL.

The fractions of minutes are given only to 34 feet in 100.

A clinometer graduated by the 3d column and numbered by the first one will give at sight the slopes in feet per 100 feet. No errors Original

Rise in ft per 100 ft hor.	Length of slope per 100 ft hor.	Angle of slope.		Rise in ft per 100 ft hor.	Length of slope per 100 ft hor.	Angle of slope.		Rise in ft per 100 ft hor.	Length of slope per 100 ft hor.	Angle of slope.

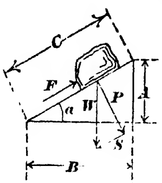
In describing **railroad grades**, it is usual, as in our tables, to refer the rise, A, to the corresponding *horizontal* length, B. We then have $\frac{\text{rise}}{\text{length}} = \frac{A}{B}$ the *tangent* of the angle, a, between the plane and the horizontal. If the rise, A, be referred to the *sloping* length, C, we have $\frac{\text{rise}}{\text{length}} = \frac{A}{C} =$ *sine* A; and this fraction is proportional to the component, S, of the weight, W, in the direction of the slope. Thus, on a grade where rise, A, = 0.1 × sloping length, C, we have $\sin a = 0.1$, and S = 0.1 W. The *tangent* of a is only *approximately* proportional to S; but the steepest grades, surmounted by traction only, even on electric railways, rarely, if ever, exceed from 13 to 15 per cent; and, on these, the error, due to using $\tan a$ instead of $\sin a$, is less than a difference of 0.2 per cent in the grade, and about – 1 per cent of the true value of S. For steeper grades, such as those of rack railways, it should always be specified whether the rise refers to the horizontal or to the sloping measurement.



Transverse slopes, such as those of earthwork, are sometimes, like railroad grades, stated in $\frac{\text{ft. vertical}}{\text{ft. horizontal}}, \frac{A}{B}$, but usually in $\frac{\text{ft. horizontal}}{\text{ft. vertical}}$, as $\frac{B}{A}$. Here $\frac{B}{A}$ is the cotangent of the angle, a, with the horizontal, or the tangent of the angle ($90° - a$) with the vertical. Thus stated, a slope of 2 to 1 means a slope of 2 horizontal to 1 vertical.

Table of grades per mile; or per 100 feet measured horizontally.

Grade in ft. per mile	Grade in ft. per 100 ft	Grade in ft. per mile.	Grade in ft. per 100 ft	Grade in ft. per mile.	Grade in ft. per 100 ft	Grade in ft. per mile	Grade in ft. per 100 ft.

If the grade per mile should consist of feet *and tenths*, add to the grade per 100 feet in the foregoing table, that corresponding to the number of tenths taken from the table below; thus, for a grade of 43.7 feet per mile, we have .81439 + .01326 = .82765 feet per 100 feet.

Ft per Mile.	Per 100 Feet.	Ft. per Mile	Per 100 Feet	Ft per Mile.	Per 100 Feet.

TABLE OF HEADS OF WATER CORRESPONDING TO GIVEN PRESSURES.

Water at maximum density, 62.425 lbs. per cubic foot = 1 gram per cubic centimeter; corresponding to a temperature of 4° Centigrade = 39 2° Fahrenheit.

Head in feet = 2.306768 × pressure in lbs. per square inch.
" " = 0.0160192 × pressure in lbs. per square foot

Heads corresponding to pressures not given in the table can be found by these formulæ, or taken from the table by simple proportion.

Pressure.		Head.	Pressure.		Head.	Pressure.		Head.

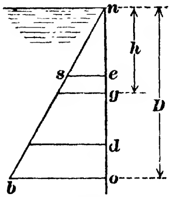
Total pressure, P, against a vert plane, $n\,o$, of unit width, y, perp to the paper, and of depth, $D = n\,o$, beginning at water surf, n. Area of plane = a $D = 2\,h$; h = depth from surf, n, to cen of grav, g, of plane, $n\,o$. Water at its max density, or w = 1 gram per cu cm = 62.425 lbs per cu ft, corresponding to a temp of 4° C = 39.2° F. Let $b\,o$ = $w\,D$ = unit pres at depth, D. Then $P = \frac{w\,D}{2}\,D = w\,h\,a$. Hence, P is represented by area of triangle, $n\,b\,o$.



With D in meters, and y = 1 meter, P, in kilograms, = $500\,D^2$.
With D in feet, and y = 1 foot, P, in pounds, = $31.2125\,D^2$.
With D in inches, and y = 1 foot, P, in pounds, = $0.21675\,D^2$.

Total pressure, P, in lbs, on vertical plane, 1 ft wide, extending from water surf to depth, D.

25	19,508	50	78,031	75	175,570	100	312,125

For depths not found in the table, we have, for any depth, D':

total pressure, P, = $\dfrac{\text{total pressure for } n\,D'}{n^2}$, where n = any number.

Thus, for a depth, D', of 8.5 feet, we may take $n = 2$. Then:

total pressure, P, = $\dfrac{\text{total pressure for } 2 \times 8.5 \text{ ft}}{4} = \dfrac{9020.4}{4} = 2255.10$ lbs

For a portion, $e\,d$, of the plane, we have, for total pressure on $e\,d$ represented by trapezoid, $d\,s$:
total pressure on $e\,d$ = total pressure on $n\,d$ — total pressure on $n\,e$.

Methods of reckoning time. Astronomers distinguish between mean solar time, true or apparent solar time, and sidereal time.

At a standard meridian (see page 267) **mean solar time** is the same as ordinary clock time. At any point not on a standard meridian, *standard* time is the local mean solar time of the meridian adopted as standard for such point; and *local* time is = time at a standard meridian *plus* correction for longitude from that meridian if the place is *east* of the meridian, and *vice versa*. For the amount of such correction, see second table above. **A true or apparent solar day** is the interval of time between two successive culminations of the sun, *i.e.*, between two successive transits or passages of the sun across the meridian of the same point on the earth; but, since these intervals are unequal, they do not correspond with the uniform movement of clock time. A fictitious or imaginary sun, called the "mean sun,' is therefore supposed to move along the equator in such a way that the interval between its culminations is constant This interval is called a day, or mean solar day, and is the average of the lengths of all the *apparent* solar days in a year. Apparent and mean time agree at four points in the year, viz, about the middle of April and of June, September 1 and December 24. The sun is sometimes behind and sometimes in advance of the mean sun, and is called "slow" or "fast" accordingly. The sun is "slow" in winter, the maximum being about February 11, when it passes any standard meridian, or "souths" (making *apparent* noon), about 14m, 28s, *after* noon by a correct clock. The sun is "fast," or in advance of the clock, in May and in the fall, with a maximum, about November 2, of about 16m, 20s.

The difference between apparent and mean time is called the **equation of time.** It can be obtained from the Nautical Almanac, or, approximately, by taking the mean between the times of sunrise and sunset, as given in ordinary almanacs.

As *solar* time is measured by the apparent daily motion of the *sun*, so *sidereal* time is measured by that of the fixed *stars*, or, more strictly speaking, by the motion of the vernal equinox which is the point where the sun crosses the equator in the spring.

* The second was formerly divided into 60 equal parts called thirds (marked ‴); but it is now divided decimally.

† The old and confusing practice of designating minutes, seconds and thirds of time (see footnote *) as ′, ″ and ‴, is no longer in vogue. Days, hours, minutes and seconds are now designated by d, h, m, and s, respectively, thus: 2d, 20h, 48m, 55.43 s., and the symbols ′ and ″ designate minutes and seconds of *arc*.

A sidereal day is the interval of time between two successive passages of the vernal equinox (or, practically, of any star) past the meridian of a given point on the earth It is, practically, the time required for one complete revolution of the earth on its axis, relatively to the stars

The length of the sidereal day is 23 h, 56 m, 4 09 s, of mean solar time or 3 m, 55 91 s of mean solar time less than the mean solar day of 24 hours. In other words, a star will, on any night, appear to set 3 m, 55 91 s earlier by a correct clock than it did on the preceding night Hence, substantially, the number of sidereal days in a year is greater by 1 than the number of solar days.

The sidereal day, like the solar day, is divided into 24 hours These hours are, of course, shorter than those of the solar day in the same proportion as the sidereal day is shorter than the solar day They are counted from 0 to 24, commencing with sidereal noon, or the instant when the vernal equinox passes the upper meridian

The civil day (= 24 hours of clock or mean solar time) commences at midnight; and **the astronomical solar day** at noon on the civil day of the same date. Thus, on a standard meridian, Thursday, May 9, 2 A M. civil time, is Wednesday, May 8, 14 h, astronomical time, but Thursday, May 9, 2 P M, civil time is Thursday, May 9, 2 h. astronomical time.

The civil month is the ordinary and arbitrary month of the calendar, varying in length from 28 to 31 mean solar days

A sidereal month is the time required for the moon to perform an entire revolution with reference to the stars Its mean length, in mean solar time, is about 27 d, 7 h, 43 m, 12 s

A lunation, or synodic month is the time from new moon to new moon. Its mean length is about 29 d, 12 h, 44 m, 3 s

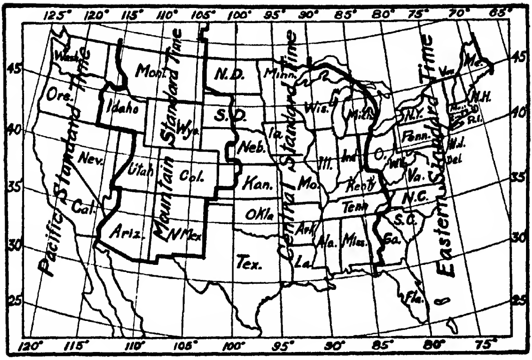
The tropical or natural year is the time during which the earth describes the circuit from either equinox to the same again Its mean length, in mean solar time, is now about 365 d, 5 h, 48 m 49 s

The sidereal year is the time during which the earth describes its orbit with reference to the stars Its mean length, in mean solar time, is about 365 d, 6 h, 9 m, 10 s

The civil year is that arbitrary or conventional and variable division of time comprised between the 1st of January and the 31st of the following December, both inclusive It contains ordinarily 365 mean solar days of 24 hours, but each year whose number is divisible by 4 contains 366 days, and is called a **leap year**, except that those years whose numbers end in 00 and are not multiples of 400 are not leap years.

To regulate a watch by the stars. The author, after having regulated his chronometer for a year by this method only differed but a few seconds from the actual time as deduced from careful solar observations Select a window facing west if possible, and commanding a view of a roof-crest or other fixed horizontal line, preferably about 40° above the horizon, in order to avoid disturbance due to refraction, and distant say 50 feet or more Note the time when any bright fixed star (not a planet) passes the range formed between the roof, etc., and any fixed horizontal line about the window frame as a pin fixed in either jamb The sight in the window, and the watch, must be illuminated The star will pass the range 3 m 55.91 s earlier on each succeeding evening Those stars which are nearest the equator appear to move the fastest, and are therefore best suited to the purpose. If the first observation of a given star be made as late as midnight, that same star will answer for about three months until at last it will begin to pass the range in daylight Before this happens, transfer the time to another star which sets later By thus tabulating, throughout the year, about half a dozen stars which follow each other at nearly equal intervals of time, we may provide a standard by means of which correct clock time may be ascertained on any clear night Experimenting in this way with two of the best **chronometers**, the author found that their *rates* varied, at times, as much as from three to eight seconds per day.

An average man takes **two steps** (one right, one left) **per second.** Hence, march music usually takes one second per measure (or "bar") Modern **watches** usually **tick** five times, and **clocks** either one, two, or four times, per second.



STANDARD TIME ZONES
of the United States

as establisht by the Interstate Commerce Commission in 1918, and as publisht in Circular C406 of the National Bureau of Standards in 1935; reckond from 75th, 90th, 105th and 120th meridians West of Greenwich.

The following table gives the times for each of 12 hours in the several zones of the U S, and in a number of cities of the world as compared with 12 noon, Eastern Standard Time:—Light-face, a.m., including 12 noon; bold-face, p.m. hours, including 12 midnight.

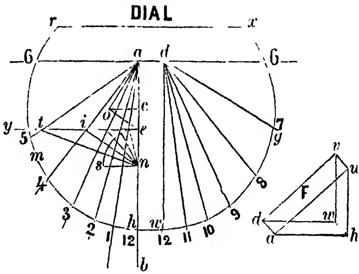
DIALLING.

To make a horizontal Sun-dial,

DRAW a line $a\ b$; and at right angles to it, draw 66. From any convenient point, as c, in $a\ b$, draw the perp $c\ o$. Make the angle $c\ a\ o$ equal to the lat of the place; also the angle $c\ o\ e$ equal to the same; join $o\ e$. Make $e\ n$ equal to $o\ e$; and from n as a center, with the rad $e\ n$, describe a quadrant $e\ s$; and div it into 6 equal parts. Draw $e\ y$, parallel to 6, 6; and from n, through the 6 points on the quadrant, draw lines $n\ t$, $n\ i$, &c, terminating in $e\ y$. From a draw lines a 5, a 4, &c, passing through t, i, &c. From any convenient point, as c, describe an arc $r\ m\ h$, as a kind of finish or border to half the dial. All the lines may now be effaced, except the hour lines a 6, a 5, a 4, &c, to a 12, or $a\ h$; unless, as is generally the case, the dial is to be divided to quarters of an hour at least. In this case each of the divisions on the quadrant $e\ s$, must be subdivided into 4 equal parts; and lines drawn from n, through the points of subdivision, terminating in $e\ y$. The quarter-hour lines must be drawn from a, as were the hour lines. Subdivisions of 5 min may be made in the same way; but these, as well as single min, may usually be laid off around the border, by eye. About 8 or 10 times the size of our Fig will be a convenient one for an ordinary dial. To draw the other half of the Fig, make $a\ d$ equal to the intended thickness of the gnomon, or style, of the dial; and draw d 12, parallel, and equal to a 12; and draw the arc $x\ g\ w$, precisely similar to the arc $r\ m\ h$. Between x and w, on the arc $x\ g\ w$ space off divisions equal to those on the arc $r\ m\ h$; and number them for the hours as in the Fig. The style F, of metal or stone, (wood is too liable to warp,) will be triangular; its thickness must throughout be equal to $a\ d$ or $h\ w$; its base must cover the space $a\ d\ h\ w$; its point will be at $a\ d$; and its perp height $h\ u$, over $h\ w$ must be such that lines $v\ d$, $u\ a$, drawn from its top, down to a and d, will make the angles $u\ a\ h$, $v\ d\ w$, each equal to the lat of the place. Its thickness, if of metal, may conveniently be from $\frac{1}{8}$ to $\frac{1}{4}$ inch; or if of stone, an inch or two, or more, according to the size of the dial. Usually, for neatness of appearance, the back $h\ u\ v\ w$ of the style is hollowed inward. The upper edges, $u\ a$, $v\ d$, which cast the shadows, must be sharp and straight. The dial must be fixed in place hor, or perfectly level; $a\ h$ and $d\ w$ must be placed truly north and south; $a\ d$ being south, and $h\ w$ north. The dial gives only sun or solar time; but clock time can be found by means of the "fast or slow of the sun," as given by all almanacs. If by the almanac the sun is 5 min &c, fast, the dial will be the same; and the clock or watch, to be correct, must be 5 min slower than it; and vice versa.



To make a Vertical Sun-Dial.

Proceed as directed above, except that the angles $c\,a\,o$ and $c\,o\,e$ on the drawing, and the angle $u\,a\,h$ or $v\,d\,w$ of the style, must be equal to the co latitude (= difference between the latitude and 90°) of the place, and the hours must be numbered the opposite way from those in the above figure; *i e.* from h to y number 12, 11, 10, 9, 8, 7; and from w to g number 12, 1, 2, 3, 4, 5. The dial plate must be placed vertically, in the position shown in the figure, facing exactly south, and with $a\,h$ and $d\,w$ vertical.

BOARD MEASURE.

Remark on following table. The table extends to 12 ins by 24 ins, but it is easy to find for greater sizes; thus, for example, the board measure in a piece of 19 by 22, will be twice that of a piece of 19 by 11, or 17 42 × 2 = 34 84 ft board meas., or that of 19¼ by 22, will be that of 10¼ by 22 added to that of 9 by 22, or 18.79 + 16.50 = 35.29. A foot of board meas is equal to 1 foot square and 1 inch thick, or to 144 cub ins. Hence 1 cub ft = 12 ft board meas.

Width in Inches.	Feet of Board Measure contained in one running foot of Scantlings of different dimensions. (Original.) 1000 ft board measure = 83⅓ cub ft. THICKNESS IN INCHES.									Width in Inches.

LAND SURVEYING.

In surveying a tract of ground, the sides which compose its outline are designated by numbers in the order in which they occur. That end of each side which first presents itself in the course of the survey, may be called its *near* end; and the other its *far* end. The number of each side is placed at its far end. Thus, in Fig. 1, the survey being supposed to commence at the corner 6, and to follow the direction of the arrows, the first side is 6, 1, and its number is placed at its far end at 1; and so of the rest. Let N S be a meridian line, that is, a north and south line; and E W an east and west line. Then in any side which runs northwardly,

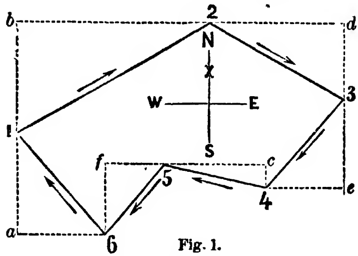

Fig. 1.

whether northeast, as side 2; or northwest, as sides 5 and 1; or due north; the distance in a due north direction between its near end and its far end, is called its *northing;* thus, *a* 1 is the northing of side 1; 1 *b* the northing of side 2; 4 *c* of side 5. In like manner, if any side runs in a southwardly direction, whether southeastwardly, as side 3; or southwestwardly, as sides 4 and 6; or due south; the corresponding distance in a due south direction between its near end and its far end, is called its *southing;* thus, *d* 3 is the southing of side 3: 3 *e* of side 4; *f* 6 of side 6. Both northings and southings are included in the general term *Difference of Latitude* of a side; or, more commonly but erroneously, its *latitude.* The distance due east, or due west, between the near and the far end of any side, is in like manner called the *easting,* or *westing,* of that side, as the case may be; thus, 6 *a* is the westing of side 1; 5 *f* of side 6; *c* 5 of side 5; *e* 4 of side 4; and *b* 2 is the easting of side 2; 2 *d* of side 3. Both eastings and westings are included in the general term *Departure* of a side; implying that the side *departs* so far from a north or south direction. We may say that a side norths, wests, southeasts, &c. We shall call the northings, southings, &c. the Ns, Ss, Es, and Ws; the latitudes, lats; and the departures, deps.

Perfect accuracy is unattainable in any operation involving the measurements of angles and distances.* That work is accurate enough, which cannot be made more so without an expenditure more than commensurate with the object to be gained. There is no great difficulty in confining the uncertainty within about one-half per cent. of the content, and this probably never prevents a transfer in farm transactions. But errors always become apparent when we come to *work out* the field notes; and since the map or plot of the survey, and the calculations for ascertaining the content, should be consistent within themselves, we do what is usually called *correcting* the errors, but what in fact is simply *humoring them in,* no matter how scientific the process may appear. We distribute them all around the survey. Two methods are used for this purpose, both based upon precisely the same principle; one by means of drawing; the other, more exact but much more troublesome, by calculation. The graphic method, in the hands of a correct draftsman, is sufficiently exact for all ordinary purposes. Add all the sides in feet together; and divide the sum by their number, for the average length. Divide this average by 8; the quotient will be the proper scale in feet per inch. In other words, take about 8 ins. to represent an average side. We shall take it for granted that an engineer does not consider it accurate work to

* A 100 ft. chain may vary its length 5 feet per mile, between winter and summer, by mere change of temperature; and this alone will make a difference of about 1 acre in 533. The student should practise plotting from perfectly accurate data; as from the example in table. p. 281, or

measure his angles to the nearest quarter of a degree, which is the usual practice among land-surveyors. They can, by means of the engineer's transit, now in universal use on our public works, be readily measured within a minute or two, and being thus much more accurate than the compass courses, (which cannot be read off so closely, and which are moreover subject to many sources of error,) they serve to correct the latter in the office. The noting of the courses, however, should not be confined to the nearest quarters of a degree, but should be read as closely as the observer can guess at the minutes. The back courses also should be taken at every corner, as an additional check, and for the detection of local attraction It is well in taking the compass bearings, to adopt as a rule, always to point the *north* of the compass-box toward the object whose bearing is to be taken, and to read off from the *north* end of the needle. A person who uses indifferently the N and the S of the box, and of the needle, will be very liable to make mistakes It is best to measure the *least* angle (shown by dotted arcs, Fig 2,) at the corners; whether it be exterior, as that at corner 5; or interior, as all the others; because it is always less than 180°, so that there is less danger of reading it off incorrectly, than if it exceeded 180°, taking it for granted that the transit instrument is graduated from the same zero to 180° each way; if it is graduated from zero to 360° the precaution is useless. When the small angle is exterior, subtract it from 360° for the interior one

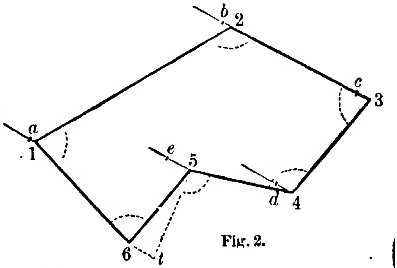

Fig. 2.

Supposing the field work to be finished, and that we require a plot from which the contents may be obtained mechanically, by dividing it into triangles, (the bases and heights of which may be measured by scale, and their areas calculated one by one,) a protraction of it may be made at once from the field notes, either by using the *angles*, or by first correcting the *bearings* by means of the angles, and then using them The last is the best, because in the first the protractor must be moved to each angle, whereas in the last it will remain stationary while all the bearings are being pricked off. Every movement of it increases the liability to errors. The manner of correcting the bearings is explained on the next page.

In either case the protracted plot will certainly not close precisely; not only in consequence of errors in the field work, but also in the protracting itself Thus the last side, No 6, Fig 2, instead of closing in at corner 6, will end somewhere else, say, for instance, at *t*; the dist *t* 6 being the *closing error*, which, however, as represented in Fig 2, is more than ten times as great, proportionally to the size of the survey, as would be allowable in practice. Now to humor-in this error, rule through every corner a short line parallel to *t* 6, and, in all cases, in the direction *from t* (wherever it may be) *to* the starting point 6 Add all the sides together, and measure *t* 6 by the scale of the plot. Then beginning at corner 1, at the far end of side 1, say, as the

Sum of all the sides	:	Total closing error *t* 6	::	Side 1	:	Error for side 1.

Lay off this error from 1 to *a*. Then at corner 2, say, as the

Sum of all the sides	:	Total closing error *t* 6	::	Sum of sides 1 and 2	:	Error for side 2.

Which error lay off from 2 to *b*; and so at each of the corners; always using, as the third term, the sum of the sides between the starting point and the given corner. Finally, join the points *a*, *b*, *c*, *d*, *e*, 6; and the plot is finished.

The correction has evidently changed the length of every side; lengthening some and shortening others It has also changed the angles. The new lengths and angles may with tolerable accuracy be found by means of the scale and protractor; and be marked on the plot instead of the old ones.

---

from those to be found in books on surveying. This is the only way in which he can learn what is meant by accurate work His semicircular protractor should be about 9 to 12 ins in diam and graduated to 10 min. His straight edge and triangle should be of metal; we prefer German silver, which does not rust as steel does; and they should be made with *scrupulous accuracy* by a skilful instrument maker. A very fine needle, with a sealing-wax head, should be used for pricking off dists and angles; it must be held vertically; and the eye of the draftsman must be directly over it. The lead pencil should be hard (Faber's No. 4 is good for protracting), and must be kept to a sharp point by rubbing on a fine file, after using a knife for removing the wood. The scale should be at least as long as the longest side of the plot, and should be made at the edge of a strip of the same paper as the plot is drawn on. This will obviate to a considerable extent, errors arising from contraction and expansion. Unfortunately, a sheet of paper does not contract and expand in the same proportion lengthwise and crosswise, thus preventing the paper scale from being a perfect corrective. In plots of common farm surveys, &c, however, the errors from this source may be neglected. For such plots as may be protracted, divided, and computed within a time too short to admit of appreciable change, the ordinary scales of wood, ivory or metal may be used; but satisfactory accuracy cannot be obtained with them on plots requiring several days, if the air be meanwhile alternately moist and dry, or subject to considerable variations in temperature. What is called *parchment* paper is worse in this respect than good ordinary drawing paper.

With the foregoing precautions we may work from a drawing, with as much accuracy as is usually attained in the field work.

When the plot has many sides, this calculating the error for each of them becomes tedious; and since, in a well-performed survey and protraction, the entire error will be but a very small quantity it should not *exceed* about $\frac{1}{400}$ part of the periphery,) it may usually be divided among the sides by merely placing about ¼, ½, and ¾ of it at corners about ¼, ½, and ¾ way around the plot, and at intermediate corners propor tion it by eye. Or calculation may be avoided entirely by drawing a line *a b* of a length equal to the united lengths of all the sides; dividing it into distances *a*, 1, 1, 2 &c equal to the respective sides. Make *b c* equal to the entire closing error join *a c*, and draw 1 1', 2, 2', &c, which will give the error at each corner.

When the plot is thus completed, it may be divided by fine pencil lines into triangles, whose bases and heights may be measured by the scale, in order to compute the contents. With care in both the survey and the drawing, the error should not *exceed* about $\frac{1}{200}$ part of the true area. At least two distinct sets of triangles should be drawn and computed as a guard against mistakes; and if the two sets differ in calculated contents more than about $\frac{1}{200}$ part, they have not been as carefully prepared as they should have been. The closing error due to imperfect field work, may be accurately calculated, as we shall show and laid down on the paper before beginning the plot, thus furnishing a perfect test of the accuracy of the protraction work, which, if correctly done, will not close at the point of beginning, but at the point which indicates the error. But this *calculation* of the error, by a little additional trouble, furnishes data also for dividing it by calculation among the diff sides besides the means of drawing the plot *correctly* at once, without the use of a protractor thus enabling us to make the subsequent measurements and computations of the triangles with more certainty

We shall now describe this process, but would recommend that even when it is employed, and especially in complicated surveys, a rough plot should first be made and corrected, by the first of the two mechanical methods already alluded to. It will prove to be of great service in using the method by calculation, inasmuch as it furnishes an eye check to vexatious mistakes which are otherwise apt to occur; for, although the principles involved are extremely simple, and easily remembered when once understood, yet the continual changes in the directions of the sides will, without great care cause us to use Ns instead of Ss, Es instead of Ws, &c

We suppose, then, that such a rough plot has been prepared, and that the angles, bearings, and distances, as taken from the field book, are figured upon it in *lead pencil*

Add together the *interior* angles formed at all the corners call their sum *a*. Mult the number of sides by 180°, from the prod subtract 360°. if the remainder is equal to the sum *a*, it is a proof that the angles have been correctly measured * This, however, will rarely if ever occur, there will always be some discrepancy, but if the field work has been performed with moderate care, this will not *exceed* about two min for each angle. In this case div it *in equal parts* among all the angles adding or subtracting, as the case may be, unless it amounts to less than a min to each angle, when it may be entirely disregarded in common farm surveys. The corrected angles may then be marked on the plot in ink, and the pencilled figures erased. We will suppose the corrected ones to be as shown in Fig 3.

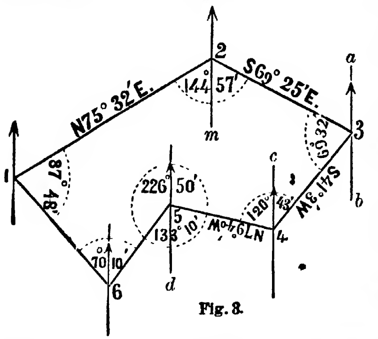

Fig. 8.

Next, by means of these corrected angles, correct the bearings also, thus, Fig 3 Select some side (the longer the better) from the two ends of which the bearing and the reverse bearing agreed; thus showing that that bearing was probably not influenced by local attraction Let side 2 be the one so selected; assume its bearing, N 75° 32' E as taken on the ground, to be correct; through either end of it, as at its far end 2, draw the short meridian line; parallel to which draw others through every corner. Now having the bearing of side 2 N 75° 32' E, and requiring that of side 3, it is plain that the reverse bearing from corner 2 is S 75° 32 W; and that therefore the angle 1, 2 *m*, is 75° 32. Therefore, if we take 75° 32 from the entire corrected angle 1, 2 3, or 144° 57', the rem 69° 25' will be the angle *m* 23; consequently the bearing of side 3 *must* be S 69° 25' E. For finding the bearing of side 4, we now have the angle 23 *a* of the reverse bearing of side 3, also equal to 69° 25'; and if we add this to the entire corrected angle 234, or to 69° 32', we have the angle *a* 34 = 69° 25' + 69° 32 = 138° 57'; which taken from 180°, leaves the angle *b* 34 = 41° 3'; consequently the bearing of side 4 *must* be S 41° 3' W. For the bearing of side 5 we now have the angle 34 *c* = 41° 3', which taken from the corrected angle 345, or 120° 43', leaves the angle *c* 45 = 79° 40'; consequently the bearing of side 5 *must* be N 79° 40' W. At corner 5, for the bearing of side 6 we have the angle 45 *d* = 79° 40', which taken from 133° 10', leaves the angle *d* 56 = 53° 30'; consequently the bearing of side 6 *must* be S 53° 30' W. And so with each of the sides, nothing be

* Because in every straight-lined figure the sum of all its interior angles is equal to twice as many right angles as the figure has sides, minus 4 right angles, or 360°.

careful observation is necessary to see how the several angles are to be employed at each corner. Rules are sometimes given for this purpose, but unless frequently used, they are soon forgotten The plot mechanically prepared obviates the necessity for such rules, inasmuch as the principle of proceeding thereby becomes merely a matter of sight, and tends greatly to prevent error from using the wrong bearings; while the protractor will at once detect any serious mistakes as to the angles, and thus prevent their being carried farther along After having obtained all the corrected bearings, they may be figured on the plot instead of those taken in the field. They will, however, require a still further correction after a while, since they will be affected by the adjustment of the closing error.

We now proceed to calculate the closing error *t* 6 of Fig 2, which is done on the principle that in a correct survey the northings will be equal to the southings, and the eastings to the westings. Prepare a table of 7 columns, as below, and in the first 3 cols place the numbers of the sides, and their corrected courses; also the dists or lengths of the sides, as measured on the rough plot, if such a one has been prepared; but if not, then as measured on the ground. Let them be as follows:

Side.	Bearing.	Dist. Ft.	Latitudes.		Departures.	
			N.	S.	E.	W.
1	N 16° 40′ W	1060	1015 5			304
2	N 75° 32′ E	1202	300.3		1163 9	
3	S 69° 25′ E	1110		390.2	1039.2	
4	S 41° 3′ W	850		641.		558.2
5	N 79° 40′ W	802	143.9			789.
6	S 53° 30′ W	705		419.3		566.7
			1459.7	1450.5	2203.1	2217.9
			1450 5			2203.1
			9.2	Error in Lat.	Error in Dep.	14.8

Now, by means of the Table of Sines, etc , find the N, S, E, W. of the several sides, and place them in the corresponding four columns Thus, for side 1, which is 1060 feet long, with bearing N 16° 40′ W ; cos 16° 40′ = 0 9580, sin 16° 40′ = 0.2868.

Here N = 1060 × 0 9580 = 1015 5; and W = 1060 × 0 2868 = 304. Proceed thus with all Add up the four cols; find the diff between the N and S cols; and also between the E and W ones. In this instance we find that the Ns are 9 2 feet greater than the Ss; and that the Ws are 14 8 ft greater than the Es; in other words, there is a closing error which would cause a correct protraction of our first three cols, to terminate 9 2 feet too far north of the starting point, and 14.8 feet too far west of it So that by placing this error upon the paper before beginning to protract, we should have a test for the accuracy of the protracting work, but as before remarked, a little more trouble will now enable us to div the error proportionally among all the Ns, Ss, Es, and Ws, and thereby give as data for drawing the plot correctly at once, without using a protractor at all

To divide the errors, prepare a table precisely the same as the foregoing, except that the hor spaces are farther apart, and that the addings-up of the *old* N, S, E, W columns are omitted. The additions here noticed are made subsequently.

The new table is on the next page.

REMARK. **The bearing and the reverse bearing** from the two ends of a line will not read precisely the same angle; and the difference varies with the latitude and with the length of the line, but not in the same proportion with either. It is, however, generally too small to be detected by the needle, being, according to Gummere, only three quarters of a minute in a line one mile long in lat 40°. In higher lats it is more, and in lower ones less. It is caused by the fact that meridians or north and south lines are not truly parallel to each other; but would if extended meet at the poles.

Hence the only bearing that can be run in a straight line, with strict accuracy, is a true N and S one, except on the very equator, where alone a due E and W one will also be straight But **a true curved E and W line** may be found anywhere with sufficient accuracy for the surveyor's purposes thus Having first by means of the N star p 284, or otherwise got a true N and S bearing at the starting point, lay off from it 90°, for a true E and W bearing *at that point* This E and W bearing will be tangent to the true E and W curve. Run this tangent carefully, and at intervals (say at the end of each mile) lay off from it (towards the N if in N lat, or vice versa) an offset whose length in *feet* is equal to the proper one from the following table, multiplied by the *square* of the distance in *miles* from the starting point These offsets will mark points in the true E and W curve.

Latitude N or S.												
5°	10°	15°	20°	25°	30°	35°	40°	45°	50°	55°	60°	65°
Offsets in ft one mile from starting point.												
.058	.118	.179	.243	.311	.385	.467	.559	.667	.795	.952	1 15	1.43

Or, any offset in ft = .6666 × Total Dist in miles^2 × Nat Tang of Lat.

A rhumb line is any one that crosses a meridian obliquely, that is, is neither due N and S, nor E and W.

Side.	Bearing.	Dist. Ft.	Latitudes. N	Latitudes. S.	Departures. E.	Departures. W.
1	N 16° 40′ W	1060	1015.5 1.7 1013.8			304.0 2.7 301.3
2	N 75° 32′ E	1202	300.3 1.9 298.4		1163.9 3.1 1167.0	
3	S 69° 25′ E	1110		390.2 1.8 392	1039.2 2.9 1042.1	
4	S 41° 3′ W	850		641.0 1.3 642.3		558.2 2.2 556.0
5	N 79° 40′ W	802	143.9 1.3 142.6			789.0 2.1 786.9
6	S 53° 30′ W	705		419.3 1.1 420.4		566.7 1.8 564.9
		5729 Sum of Sides.	1454.8 Cor'd Ns	1454.7 Cor'd Ss	2209.1 Cor'd Es	2209.1 Cor'd Ws.

Now we have already found by the old table that the Ns and the Ws are too long; consequently they must be shortened; while the Ss, and Es, must be lengthened, all in the following proportions: As the

Sum of all the sides : Any given side :: Total err of lat or dep : Err of lat or dep. of given side.

Thus, commencing with the lat of side 1, we have, as

Sum of all the sides. 5729 : Side 1. 1060 :: Total lat err. 9.2 : Lat err of side 1. 1.7

Now as the lat of side 1 is north, it must be shortened; hence it becomes = 1015.5 — 1.7 = 1013.8, as figured out in the new table. Again we have for the departure of side 1,

Sum of all the sides. 5729 : Side 1. 1060 :: Total dep err. 14.8 : Dep err of side 1. 2.7

Now as the dep of side 1 is west, it must be shortened; hence it becomes 304 — 2.7 = 301.3, as figured out in the new table.

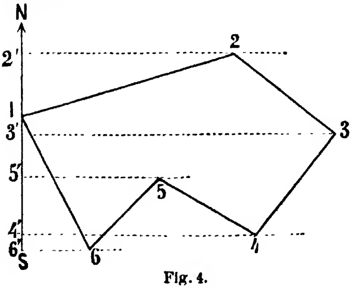

Fig. 4.

Proceeding thus with each side, we obtain all the corrected lats and deps as shown in the new table; where they are connected with their respective sides by dotted lines; but in practice it is better to cross out the original ones when the calculation is finished and proved. If we now add up the 4 cols of corrected N, S, E, W, we find that the Ns = the Ss; and the Es = the Ws, thus proving that the work is right. There is, it is true, a discrepancy of .1 of a ft between the Ns, and the Ss; but this is owing to our carrying out the corrections to only one decimal place; and is too small to be regarded. Discrepancies of 3 or 4 tenths of a foot will sometimes occur from this cause; but may be neglected. The corrected lats and deps must evidently change the bearing and distance of every side; but without knowing either of these, we can now plot the survey by means of the corrected

lats and deps alone. The principal is self-evident, explaining itself. First draw a meridian line N S, Fig. 4; and upon it fix on a point 1, to represent the *extreme west* corner* of the survey.

Then from the point 1, prick off by scale, northward, the dist 1, 2′=the corrected northing 298.4 of side 2, taken from the last table; from 2′ southward prick off the dist 2′, 3′, the corrected southing 392 of side 3, from 3′ southward prick off 3′, 4′,=southing 642 3 of side 4; from 4′ northward prick off 4′, 5′=northing 142.6 of side 5, from 5′ prick off southward 5′, 6′=southing of side 6†. Then from the points 2′, 3′, 4′, 5′, 6′, draw indefinite lines due eastward, or at right angles to the meridian line. Make by scale, 2′, 2=corrected departure of side 2; and join 1, 2. Make 3′, 3=dep of side 2+dep of side 3; and join 2, 3; make 4′, 4=3′, 3—dep of side 4, and join 3, 4; make 5′, 5=4′, 4—dep of side 5; and join 4, 5; make 6′, 6=5′, 5—dep of side 6; and join 5, 6 ‡ Finally join 6, 1; and the plot is complete If scrupulous accuracy is not required, the contents may be found by the mechanical method of triangles; the bearings, by the protractor; and the lengths of the sides, by the scale; all with an approximation sufficient for ordinary purposes; and perhaps quite as close as by the method by calculation, when, as is customary, the bearings are taken only to the nearest quarter of a degree. We have already said that with a scale of feet per inch $=\frac{\text{average length of sides}}{8}$, the error of area need not *exceed* the $\frac{1}{200}$th part.

But if it is required to calculate the area of the corrected survey with rigorous exactness, it may be done on the following principle, (see Fig 5) If a meridian line N S be supposed to be drawn through the extreme west corner 1 of a survey, and lines (called *middle distances*) drawn (as the dotted ones in the Fig) at right angles to said meridian, from the *center* of each side of the survey; then if each of the middle dists of such sides as have northings, be mult by the corrected northing of its corresponding side, and if each of the middle dists of such sides as have southings, be mult by the corrected southing of its corresponding side; if we add all the north prods into one sum; and all the south prods into another sum; and subtract the least of these sums from the greatest, the rem will be the area

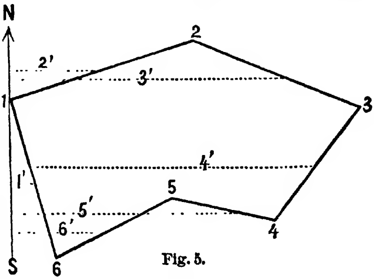

Fig. 5.

* The extreme east corner would answer as well, with a slight change in the subsequent operations, as will become evident.

† Instead of pricking off these northings and southings in succession, *from each other*, it will be more correct in practice to prepare first a table showing how far each of the points 2′,3′, &c, is north or south from 1. This being done, the points can be pricked off north or south from 1, without *moving the scale each time;* and of course with greater accuracy. Such a table is readily formed. Rule it as below, and in the first three columns place the numbers of the sides (starting with side 2 from point 1,) and their respective corrected northings and southings The formation of the 4th and 5th cols by means of the 3d and 4th ones, explains itself. Its accuracy is proved by the final result being 0.

Side.	N. lat.	S. lat.	Dist N or S from Point 1. N.	S.
2	298.4		298.4	
3		392.		93.6
4		642.3		735.9
5	142.6			593.3
6		420.4		1013.7
1	1013.8		000.0	000.0

‡ A similar table should be prepared beforehand for the dists of the points 2, 3, 4, &c, east from the meridian line. It is done in the same manner, but requires one col less, as all the dists are on the same side of the mer line. Thus, starting from point 1, with side 2.

Side.	E dep.	W. dep.	Dist east from meridian line.
2	1167.0		1167.0
3	1042.1		2209.1
4		556.0	1653.1
5		786.9	866.2
6		564.9	301.3
1		301.3	000.0

This work likewise proves itself by the final result being 0.

of the survey.* The corrected northings and southings we have already found; as also the eastings and westings. The middle dists are found by means of the latter, by employing their *halves*; adding half eastings, and subtracting half westings. Thus it is evident that the middle dist 2' of side 2, is equal to half the easting of side 2. To this add the other half easting of side 2, and a half easting of side 3, and the sum is plainly equal to the middle dist 3 of side 3. To this add the other half easting of side 3, and subtract a half westing of side 4, for the middle dist 4 of side 4. From this subtract the other half westing of side 4, and a half westing of side 5, for the middle dist 5' of side 5, and so on. The actual calculation may be made thus.

Half easting of side 2 = $\frac{1167}{2}$ = 583 5 E = mid dist of side 2.
583 5 E
————
Half easting of side 3 = $\frac{1042 1}{2}$ = 1167 0 E
521 0 E
————
1688 0 E = mid dist of side 3.
521 0 E
————
Half westing of side 4 = $\frac{556}{2}$ = 2209 0 E
278 0 W
————
1931 0 E = mid dist of side 4
278 0 W
————
Half westing of side 5 = $\frac{786 9}{2}$ = 1653 0 E
393 5 W
————
1259 5 E = mid dist of side 5
393 5 W
————
Half westing of side 6 = $\frac{564 9}{2}$ = 866 0 E
282 4 W
————
583 6 E = mid dist of side 6.
282 4 W
————
Half westing of side 1 = $\frac{301.3}{2}$ = 301 2 E
150 6 W
————
150.6 E = mid dist of side 1.

The work always proves itself by the last two results being equal.

Next make a table like the following, in the first 4 cols of which place the numbers of the sides, the middle dists, the northings, and southings. Mult each middle dist by its corresponding northing or southing, and place the products in their proper col. Add up each col, subtract the least from the

Side.	Middle dist.	Northing.	Southing.	North prod.	South prod.
1	150.6	1013.8		152678	
2	583.5	298.4		174116	
3	1688		392		661696
4	1931		642.3		1240281
5	1259.5	142.6		179605	
6	583 6		420.4		245345
				506399	2147322
					506399
					43560)1640923(37.67 Acres.

* *Proof.* To illustrate the principle upon which this rule is based, let *a b*, *b c*, and *c a*, Fig 6, represent in order the 3 sides of the triangular plot of a survey, with a meridian line *d f* drawn through the extreme west corner, *a*. Let lines *b d* and *c f* be drawn from each corner, perp to the meridian line; also from the middle of each side draw lines *w e*, *m n*, *s o*, also perp to meridian; and representing the middle dists of the sides. Then since the sides are regarded in the order *a b*, *b c*, *c a*, it is plain that *a d* represents the northing of the side *a b*; *f a* the northing of *c a*; and *d f* the southing of *b c*. Now if we mult the *northing a d* of the side *a b*, by its mid dist *e w*, the prod is the area of the triangle *a b d*. In like manner the *northing f a* of the side *c a*, mult by its mid dist *s o*, gives the area of the triangle *a c f*. Again, the *southing d f* of the side *b c*, mult by its mid dist *m n*, gives the area of the entire fig *d b c f d*. If from this area we subtract the areas of the two triangles *a b d*, and *a c f*, the rem is evidently the area of the plot *a b c*. So with any other plot, however complicated.

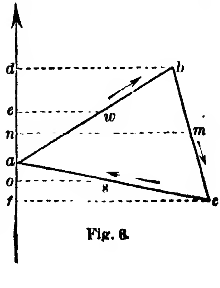

Fig. 6.

greatest. The rem will be the area of the survey in sq ft; which, div by 43560, (the number of sq ft in an acre,) will be the area in acres, in this instance, 37 67 ac.

It now remains only to calculate the corrected bearings and lengths of the sides of the survey, all of which are necessarily changed by the adoption of the corrected lats and deps. To find the bearing of any side, div its departure (E or W) by its lat (N or S), in the table of nat tang, find the quot; the angle opposite it is the reqd angle of bearing. Thus, for the course of side 1, we have $\frac{301.3 \text{ W}}{1013.8 \text{ N}}$ = .2972 = nat tang, opposite which in the table is the reqd angle, 16° 33′; the bearing, therefore, is N 16° 33′ W.

Again: for the dist or length of any side, from the table of nat cosines take the cos opposite to the angle of the corrected bearing, divide the corrected lat (N or S) of the side by the cos. Thus for the dist of side 1, we find opposite 16° 33′, the cos .9586 And

$$\overset{\text{Lat.}}{1013.8} \div \overset{\text{Cos.}}{.9586} = 1057.6 \text{ the reqd dist.}$$

The following table contains all the corrections of the foregoing survey; consequently, if the bear-

Side.	Bearing.	Dist. Ft.
1	N 16° 33′ W	1057.6
2	N 75° 39′ E	1204.0
3	S 69° 23′ E	1113.3
4	S 40° 53′ W	849.6
5	N 79° 44′ W	800.1
6	S 53° 21′ W	704.3

ings and dists are correctly plotted they will close perfectly. The young assistant is advised to practise doing this, as well as dividing the plot into triangles, and computing the content. In this manner he will soon learn what degree of care is necessary to insure accurate results

The following **hints** may often be of service.

1st. Avoid taking bearings and dists along a circuitous boundary line like *a b c*, Fig 7, but run the straight line *a c*; and at right angles to it, measure offsets to the crooked line. **2d.** Wishing to survey a straight line from *a* to *c*, but being unable to direct the instrument precisely toward *c*, on account of intervening woods, or other obstacles; first run a trial line, as *a m*, as nearly in the proper direction as can be guessed at.

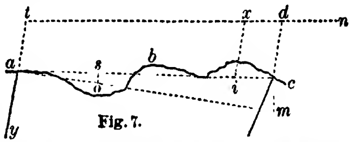

Fig. 7.

Measure *m c*, and say, as *a m* is to *m c*, so is 100 ft to ? Lay off *a o* equal to 100 ft, and *o s* equal to ?; and run the final line *a s c*. Or, if *m c* is quite small, calculate offsets like *o s* for every 100 ft along *a m*, and thus avoid the necessity for running a second line. **3d.** When *c* is visible from *a*, but the intervening ground difficult to measure along, on account of marshes, &c, extend the side *y a* to good ground at *t*: then making the angle *y t d* equal to *y a c*, run the line *t n* to that point *d* at which the angle *n d c* is found by trial to be equal to the angle *a t d*. It will rarely be necessary to make more than one trial for this point *d*, for, suppose it to be made at *x*, see where it strikes *a c* at *i*, measure *i c*, and continue from *x*, making *x d* = *i c*. **4th.** In case of a very irregular piece of land, or a lake, Fig 8, surround it by straight lines. Survey these, and at right angles to them, measure offsets to the crooked boundary

Fig. 8.

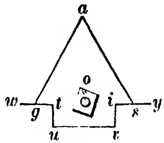

Fig. 9.

Fig. 10.

5th. Fig 9 Surveying a straight line from *w* toward *y*, an **obstacle**, *o*, is met. To pass it, lay off a right angle *w t u*, measure any *t u*, make *t u v* = 90°, measure *u v*; make *u v i* = 90°, make *v i* = *t u*, make *v i y* = 90°. Then is *t i* = *u v*, and *i y* is in the straight line. Or, with less trouble, at *g* make *t g a* = 60°, measure any *g a*; make *g a s* = 60°; and *a s* = *g a*, make *a s i* = 60°. Then is *g s* = *g a* or *a s*; and *i s*, continued toward *y*, is in the straight line. **6th** Fig 10. Being between two objects, *m* and *n*, and wishing to place myself in range with them, I lay a straight rod *c b* on the ground, and point it to one of the objects *m*; then going to the end *c*, I find that it does not point to the other object, *n*. By successive trials, I find the position *e d* in which it points to both objects, and consequently is in range with them.

CHAINING.

Chains. Engineers have abandoned the Gunter's chain of 66 ft, divided into 100 links of 7.92 ins each. They now use a chain of 100 ft, with 100 links of 1 ft each, and calculate areas in sq ft, the number of which, divided by 43,560, reduces to acres and decimals, instead of to acres, roods, and perches. Gunter's chain is used on U. S. Government land surveys.

Chains are commonly made of iron or steel wire. Each link is bent at each of its ends, to form an eye, by which it is connected with the adjacent links, either directly, as in the Grumman patent chain, or, more commonly, by from 1 to 3 small wire links. The wear of these links is a fruitful source of inaccuracy, inasmuch as even a very slight wear of each link considerably increases the length of the chain. Hence, chains should be compared with some standard, such as a target rod, every few days while in use. For transportation, the lengths are folded on each other, making a compact and sheaf-like bundle.

Tapes. With improved facilities for the manufacture of steel tape, the chain is going out of use. The tape, being much lighter, requires much less pull, and, as there are no links to wear, its length is much more nearly constant than that of the chain. It is replacing, to some extent, the base-measuring rod for accurate geodetic work. Steel tapes are made in continuous lengths up to 500, 600, and even 1000 ft, but those of 100 ft are the most commonly used. Very long tapes are liable to breakage in handling. Even the shorter lengths, unless handled carefully, are apt to kink and break. Breaks are difficult to mend, and the repaired joint is seldom satisfactory; whereas a kink in a wire chain seldom involves more than a temporary change of length. Being run over by a car or wagon will often kink steel tapes very badly, if it does not break them.* However, the lightness, neatness, and reliability of the tape offset these disadvantages, which, indeed, the surveyor soon learns to overcome.

Tapes for general field work are usually narrow (from 0.10 to 0.25 in) and thick (from 0.013 to 0.025 in),† and are graduated by means of small brass and copper rivets, spaced, in general, 5 ft apart, 1 ft apart in the 10 ft at each end, and 0.1 ft apart in the ft at each end. They are usually mounted on reels.

Tapes for city work are wider (from 0.25 to 0.5 in) and thinner (from 0.007 to 0.010 in)† and are graduated (usually to 0.01 ft) throughout their length by means of lines and numerals etched on the steel.

Pins are ordinarily of wire, pointed at the lower end, and bent to a ring at the upper end. They can be forced into almost any ground that is not exceedingly stony. A steel ring, like a large key ring, is often used for carrying the pins. Each pin should have a strip of bright red flannel tied to its top, in order that it may be readily found, among the grass, etc., by the rear chainman.

Corrections for Sag and Stretch. The following diagram‡ (see p. 283) gives the correction for a steel tape weighing 0.75 lb per 100 ft.†

---

*The Nichols Engineering & Contracting Co., Chicago, guarantees that its tapes will not be injured by being run over by wagons.

†The sizes of tapes, as made by different manufacturers, vary greatly. In applying the corrections, therefore, the width and thickness of the tape to be used should be carefully measured, and its weight per ft computed.

‡Deduced from diagrams constructed by Mr. J. O. Clarke, Proceedings Engineers' Club of Philadelphia, April, 1901, Vol. XVIII, No. 2. from the formula:

$$\text{Stretch, in feet} = \frac{PS}{EA}$$

where

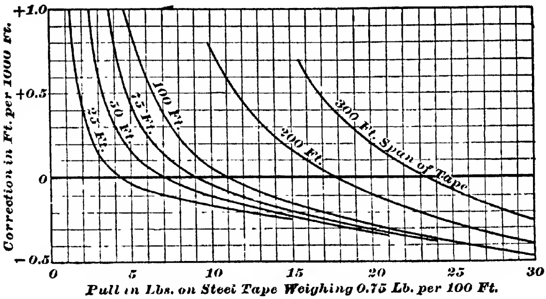
P = pull on tape, in lbs.
S = span of tape, in feet.
E = modulus of elasticity for steel = 27,500,000 lbs per sq in.
A = area of cross-section of tape weighing 0.75 lb per 100 ft.
= 0.0022 square ins,

and from the equation of the parabola, according to which

$$\text{shortening by sag, in feet} = \frac{W^2\ S^3}{24\ P^2}$$

where W = weight of tape, in pounds per foot.

Except for very light pulls, this last formula gives practically the same results as the equation of the catenary, which is absolutely correct, but much more cumbersome.



The diagram shows that a span of 100 ft of tape weighing 0 75 lb per 100 ft, requires a pull of 11 2 lbs to reduce the correction to zero; a span of 50 ft, 7.3 lbs, etc. At these tensions (which are called normal pulls), the opposite effects of sag and of stretch are equal. At higher tensions, the lengthening due to stretch exceeds the shortening due to sag, and vice versa.

Tapes of other weights require pulls proportional to their weights or to their areas of cross-section. Thus, a tape, of any length, weighing 1 lb per 100 ft, would require, for any given correction, a pull of $x = \frac{100}{75} y = 1\frac{1}{3} y$, where y = the pull for the same correction on the standard tape, weighing 0.75 lb per 100 ft.

Conversely; given a pull of 10 lbs on a 50 ft span of a tape weighing 0 6 lb per 100 ft; required the correction. To produce the same error in the tape weighing 0.75 lb per 100 ft would require a pull of $y = 10 \times \frac{75}{60} = 12.5$ lbs. Referring to the diagram at 12.5 lbs on the curve for a 50 ft span, we find correction = −0.16. This is the proper correction for either the heavier tape with 12.5 lbs or for the lighter tape with 10 lbs pull.

Corrections for temperature. Tapes are usually graduated so as to be of standard length at 62° Fahr. For ordinary steel tape, the correction for temperature is about 0.0000065 ft per ft per degree Fahr.

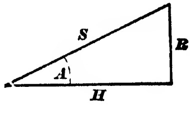
Corrections for temperature are uncertain, since the temperature of the tape cannot be determined with any accuracy. Measurements requiring great accuracy should therefore be made in cloudy weather, or at night, and the tape and the thermometer should be kept off the ground.

When measuring over **sloping ground**, in ordinary work, the chain or tape should be held as nearly horizontal as possible, transferring the position of the raised end to the ground by means of a plumb line. Where the ground is steep, it becomes necessary to use a short length of tape, as the down-hill chainman could not otherwise hold his end high enough; or the tape may be held parallel with the slope, and the distance corrected by the following formulas:

$\frac{H}{S} = \cos A$; $H = S. \cos A$; $S = \frac{H}{\cos A} = H. \sec A$;

$\frac{R}{H} = \tan A$; $R = H. \tan A$;

$\frac{R}{S} = \sin A$; $R = S. \sin A$.



LOCATION OF THE MERIDIAN.

By means of circumpolar stars.

(1) Seen from a point O (Figs. 1 and 2) on the earth, a circumpolar star (star near the pole *P*) appears to describe daily* and counterclockwise a small circle, *e u w l*, about the pole. The angle P O *e*, P O *u*, etc., subtended by the radius P *e*, P *u*, etc., of this circle, or the apparent distance of the star from the pole, is called its **polar distance.** The polar distances of stars vary slightly from year to year. See Table 3. They vary slightly also *during* each year. In the case of Polaris this latter variation amounts to about 50 seconds of arc.

(2) The **altitude** of the pole is the angle N O P of the pole's elevation above the horizon N E S W, and is = the **latitude** of the point of obser-

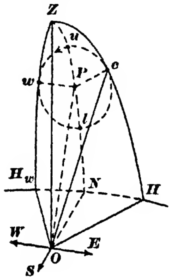


FIG. 1.

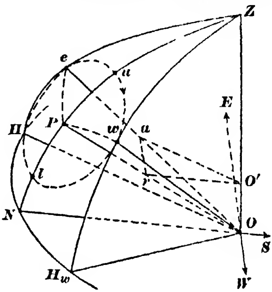

FIG. 2.

vation. **Declination** = angular distance north or south from the celestial equator. Thus, declination of pole = 90°. Declination of any star = 90°—its polar distance.

(3) Let Z *e* H be an arc of a vertical circle† passing through a circumpolar star, *e*, and let H be the point where this arc meets the horizon N E S W. Then the angle N Z H at the zenith Z, or N O H at the point O of observation, between the plane N Z O of the meridian and the plane H Z O of the star's vertical circle (or the arc N H), is called the **azimuth**‡ of the star. If this angle N O H be laid off from O H, on the ground, the line O N will be in the plane of the **meridian** N Z S, or will be a **north-and-south line.**‖

(4) When a star is on the meridian Z N of the observer, above or below the pole P, as at *u* or *l*, it is said to be at its **upper or lower culmination,** respectively. Its azimuth is then = 0, the line O H coinciding with the meridian line O N.

(5) When the star has reached its greatest distance east or west from the pole, as at *e* or *w*, it is said to be at its **eastern** or **western elongation.**§

---

* In 23 h. 56.1 m.

† A great circle is that section of the surface of a sphere which is formed by a plane passing through the center of the sphere. A vertical circle is a great circle passing through the zenith Z.

‡ Astronomers usually reckon azimuth from the south point around through the west, north, and east points, to south again; but for our purpose it is evidently much more convenient to reckon it from the north point, and either to the east or to the west, as the case may be.

‖ The point N, on the horizon, is called the **north point,** and must not be confounded with the north *pole* P.

§ As seen from the equator, a star, at either elongation, is, like the pole itself, on the horizon; and the two lines P *e*, P *w*, joining it with the pole, form a single straight line perpendicular to the meridian, and lying in the

(6) The **hour angle** of any star, at any given moment, is the time which has elapsed since it was in upper culmination.*

(7) Evidently the azimuth of a star is continually changing. In circumpolar stars it varies from 0° to maximum (at elongation) and back to 0° twice daily, as the star appears to revolve about the pole; but when the star is near either elongation the change in azimuth takes place so slowly that, for some minutes, it is scarcely perceptible, the star appearing to travel vertically.

(8) For any star, whose declination (= 90° — its polar distance) exceeds the latitude of the point of observation, we have: †

$$\left.\begin{array}{l}\text{Sine of azimuth of star}\\ \text{at elongation}\end{array}\right\} = \frac{\text{sine of polar distance of star}}{\text{cosine of latitude of point of observation}}$$

or see (11) and Table 3. When lat > decl, sine az > 1. Hence this formula does not then apply.

(9) The following circumpolar stars are of service in connection with observations for determining the meridian. See Fig. 3.

Constellation	Letter	Called
Ursa minor (Little bear)	α (alpha)	Polaris
Ursa major (Great bear)	ε (epsilon)	Alioth
" " (" ")	ζ (zeta)	Mizar
Cassiopeia	δ (delta)	Delta ‡

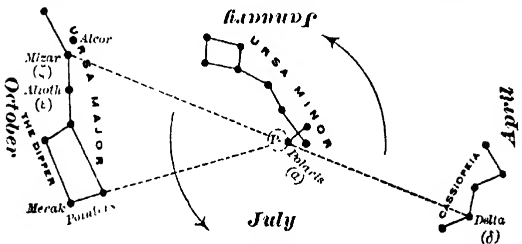

FIG. 3.

(10) **Polaris**, or the **north star**, is fortunately placed for the determination of the meridian, its polar distance being only about 1 °. See Table 3. Fig. 3 shows the circumpolar stars as they appear about midnight in July; inverted, as in January; with the left side uppermost, as in April; and, with the right side uppermost, as in October.‖

---

horizon. The azimuth of the star is then = its polar distance. But in other latitudes P e and P w form acute angles with the meridian, as shown, and these angles decrease, and the azimuth of the star at elongation increases, as the latitude increases.

* In lat. 40° N., the hour angle, Z P e = Z P w, of Polaris, at elongation, is = 5 h 55 m. of solar time. **Caution.** It will be noticed that, except for an observer at the equator, the elongations do *not* occur at 90° from the meridian.

† In the spherical triangle Z P e, we have:

$$\frac{\sin e\,Z\,P}{\sin Z\,e\,P} = \frac{\sin P\,e}{\sin P\,Z}$$

But, since Z e P = 90°, sin Z e P = 1. Also, sin P Z = cos (90 − P Z), and e Z P = azimuth of e.

$$\text{Hence, sin azimuth of } e = \frac{\sin P\,e}{\sin P\,Z} = \frac{\text{sin polar distance } P\,O\,e}{\text{cos latitude}}$$

‡ δ Cassiopeia is here called Delta, for brevity.

‖ **Polaris is easily found** by means of the two well-known stars called the "**pointers**" in "the dipper," Fig. 3, which forms the hinder

(11) Table 3 gives the mean polar dists of Polaris and their log sines for Jan 1st in each second year from 1936 to 1956 incl, the log cosines of each fifth degree of lat from 25° to 50°, and the corresponding azimuths of Polaris at elongation. Intermediate values may be taken by interpolation.

(12) **By Observation of Polaris at Elongation.** This method has the convenience, that at and near elongation the star appears to travel vert'y for some minutes, its azimuth, during that time, remaining practically constant; but during certain parts of the year (see Table 1), the elongations of Polaris take place in daylight; so that this method cannot then be used (See note p. 290). See (18), (19), (22). Nor can it be used at any time in places south of about 4° N lat, because there Polaris is not visible.

(13) The approx times of elongation of Polaris for the first of each month in 1937 are given in Table 1, with instructions for finding the times for other dates. Or, watch Polaris in connection with any of those stars which are nearly in line with it and the pole, as Delta, Mizar, and Alioth. See Fig 3. The time of elongation is approximated, with sufficient closeness for the determination of the azimuth, by the cessation of apparent hor motion during the observation.

(14) From 15 to 30 minutes before the time of elongation, have the transit, see (21), set up and carefully centered over a stake previously driven and marked with a center point. The transit must be in adjustment, espec'y in regard to the second adjustment, p 294, or that of the hor axis, by which the line of collimation is made to describe a vert plane when the transit is leveled and the telescope is swung upward or downward.

(15) Means must be provided for making the stake and cross-hairs of the transit visible. This may be done quite satisfactorily by holding a sheet of paper behind the stake, and then illuminating the paper by a light held either behind the paper or in front of it, but not so that the light is in the field of the instrument. In this way, the stake and pencil point or knife-blade held on it, or the nail or tack in its top, and also the cross-hairs, are all seen in silhouet against the illuminated paper. Care should be taken, however, not to use the wrong cross-hair.

(16) Bring the vert hair to coincide with Polaris, and, by means of the tangent screw, follow the star as it appears to move, to the *right* if approaching *eastern* elongation, or *vice versa*, keeping the hair upon the star, as nearly as may be. As elongation is approacht, the star will appear to move more and more slowly in azimuth. When it appears to travel vert'y along the hair, it has reacht elongation, and the vert plane of the transit is in the plane of the star's vert circle at elongation. Depress the telescope, and fix a point in the line of sight, preferably 300′ or more distant from the transit. Immediately reverse the transit, (swinging it hor'y thru an arc of 180°), sight the star again, again depress, and, if the line of sight then coincides perfectly with the mark first set, both are in the plane of the star's vert circle. If not, note where the line of sight does strike, and make a third mark midway betw the two. The line of sight, when directed to this third mark, is in the req'd plane, from which the azimuth, found as in (8), has yet to be laid off to the meridian, to the *left* from *eastern* elongation, and *vice versa*.

---

portion of the "great bear" (Ursa major), a line drawn through these two stars passing near Polaris. As the stars in the handle of the dipper form the tail of the great bear, as shown on celestial maps, so Polaris and the stars near it form the tail of the little bear (Ursa minor.) Polaris is also nearly midway and in line between Delta and Mizar. Polaris forms, with three other and less brilliant stars, a quite symmetrical cross, with Polaris at the end of the right arm. In Fig. 3 this cross is inverted. Its height is about 5°, or = the distance between the pointers.

(17) To avoid driving the distant stake and marking it during the night, a fixt target at any convenient point may be used, and the hor angle formed betw the line of sight to the star and that to the target merely noted, for use in ascertaining and laying off the azimuth of the target.

(18) **By observations of Polaris at Culmination.** Fig 3. See parag 9. The times of Polaris at culmination may be determined by the table below* in which are given the number of minutes (and tenths) to the culmination of Polaris *after* its being in the same vert plane with Delta Cassiopeiae or Mizar†.

	Jn 1	Fb 1	Mr 1	Ap 1	My 1	Jn 1	Jl 1	Ag 1	Ag 1	Sp 1	Oc 1	Nv 1	Dc 1	Jn 1

In lat 50°, the time interval is 0.1 min greater than in lat 40°.
In lat 15°, the time interval is 0.1 minute less than in lat 30°.
The mean annual increase after 1942 is 33 secs, or 0.55 minute.

(19) **By observation of Polaris at any point in its path.** Table 1 gives the mean solar times of upper culmination of Polaris on the 1st of each month in 1937, and directions for ascertaining the times on other dates; and Table 2 gives the azimuths of Polaris corresponding to different values of its hour angle in civil or mean solar time, for different latitudes from 30° to 50°, and for Jan 1, 1938 and 1948. For hour angles, latitudes and dates intermediate of those in the table, the azimuths may be taken by interpolation. See caution and formula, p 290.

(20) The local‡ time of observation must be accurately known, and the time of the nearest upper culmination subtracted from it. The difference is the hour angle to be used in Table 2; the resulting azimuth is to the west of north if the hour angle is positive, and to the east of north if negative. Find the time of the nearest upper culmination from Table 1. For the months where only lower culminations are given, add or subtract 11 hours, 58 minutes.

(21) Where great accuracy is not req'd, Polaris may be observed by means of a plumb-line and sight. A brick, stone or other heavy object will answer perfectly as a plumb-bob. It should hang in a pail of water. A compass sight, or any other device with an accurate straight slit about $\frac{1}{16}$″ wide may be used. The sight must always remain perfectly vert, but must be adjustable hor'y for a few feet east and west. The plumb-line and sight should be at least 15 feet apart, and so placed that the star and plumb-line can be seen together thru the sight, thruout the observation. The plumb-line must be illuminated. It is well to arrange these matters on an evening preceding that of the observation. When the star reaches elongation, the sight must be fastened in range with the plumb-line and star. From the line so obtained, lay off the azimuth; to the *west* for *east* elongation, and *vice versa*.

* Taken from p 767 of the American Ephemeris and Nautical Almanac of 1937, by interpolation.

† Mizar may be recognized by the small star Alcor close to it.

‡ **Local time** agrees with standard time (p 267) on the standard meridians only. For other points *add* to standard time 4 minutes for each degree of longitude *east* of a standard meridian, and *vice versa*.

(22) **By any star at equal altitudes.** This method, applicable to south as well as to north lats, consists in observing a star when it is at any of two equal altitudes, E and W of the meridian, thus locating, on the horizon, two points of equal and opposite azimuth. The meridian is midway between them.

(23) **By equal shadows from the sun.** Approximate. Hang a plum-bob, as from a tripod, in the cord of which a knot has been tied, over a convenient spot on a level surface, where the sun will shine on it for several hours before and after noon. Or a card or metal plate with a hole in it may be suspended in place of the knot. The resulting shadow of the knot or image of the sun will trace a flat curve on the level surface. From the spot under the plum-bob, draw on the level surface one or more circles with a radius of a few feet. As the shadow of the knot or the image of the sun travels over the surf, note where it intersects the circle or circles. A point midway between the extreme intersections of each circle will be due north of the point under the plum-bob at the solstices (about June 21 and Dec 21). At the vernal equinox (Mar. 21) the line thus located will then be west, and at the autumnal equinox (Sep. 21) east, of the meridian, by less than 2½ minutes of arc. For intermediate dates the error is nearly proportional to the time elapst.

Table 1

Approx local times of elongation and culmination of Polaris in lat 40° N, long 90° W from Greenwich, on first of each month 1937.

P. M. times (from noon until midnight) are printed in **bold-face.**

This table serves, with Table 3, for observations of Polaris at elongation (parag 16); and with Table 2 for any point in its path (parag 19).

In lat 25°, W elongations occur later and E earlier by 1½ mins.

In lat 50°, W elongations occur earlier and E later by 1½ mins.

In long 60°, elong'ns and culm'ns occur later by ⅓ minute.

In long 120°, elong'ns and culm'ns occur earlier by ⅓ minute.

For other days of the month, deduct 3.94 mins for each succeeding day, or add 3.94 mins for each earlier day.

Each Feb 29 makes each succeeding date occur one day later than it otherwise would, for which day 3.94 mins must be deducted.

Wherefore, for later years, add 1.6 min each year, and deduct 3.94 min for each Feb 29, when it occurs. More exactly, for 1941, four years later, including a Feb 29, the correction to add is 2.37 mins; for 1945, 4.82 mins; for 1949, 7.37 mins, etc. The corrections to be added are as follows, to the nearest minute:—

Year	1938	'39	1940 Jn-Fb	1940 Mr-Dc	1941	'42	'43	1944 Jn-Fb	1944 Mr-Dc	1945	'46	'47
Mins	2	3	5	1	2	4	6	7	3	5	6	8

At culmination, where azimuth change is most rapid, a time error of 1 min in observing Polaris involves an azimuth error of 0.3′ in lat 25° to 0.4′ in lat 50°.

Table 2.

At elonga'n, a time error of	20	10	5	1 mins,
causes an azimuth error of	16 to 21	4 to 5	1	0.4 secs.

In all latitudes, each lower culmination follows an upper culmination and precedes the next one by 11 hrs 58 mins, mean solar time. Each E elongation precedes, and each W elongation follows, the corresponding upper culmination by from 5 hrs 57 mins in lat 25° to 5 hrs 54 mins in lat 50°.

Table 3. See parag (11), p 286.

POLAR DISTANCES, AND AZIMUTHS AT ELONGATION.

Owing to variations in the place of Polaris during the year, the azimuths given in table 3 above may be in error by as much as half a minute in Lat 40°, and more for higher latitudes.

Corrections:—The azimuths given in the table are correct for April and October For January, add 24″ in Lat 25°, 30″ in Lat 40°, and 36″ in Lat 50°; for July, subtract the same amounts; obtaining the correction for any intervening month by interpolation.

Having the north polar distance p of Polaris, and the latitude L of the point of observation, the **azimuth** A of Polaris, corresponding to any **siderial-time hour angle,** H, **may be found** by the following formulas:—

$$\tan m = \tan p \cdot \cos H, \text{ then } \tan A = \frac{\sin p \cdot \sin H}{\cos (L + m)}.$$

Sidereal hour angles = 366/355 of the mean-time hour angles of Table 2.

For greater accuracy, instead of Tables 2 or 3, use the above formulas, taking the declination of Polaris (complement of its polar distance) from the American Ephemeris and Nautical Almanac, which gives them to a fraction of a second for each day of the year.

Caution. For greater assurance against error, where great accuracy is desired, it is well to use more than one method and compare the results. For example, observe Polaris both E and W of the meridian, and a star at equal altitudes south of the zenith.

NOTE.—If Polaris be found during twilight, in the morning or evening, observations of it may be made without artificial illumination of the cross-hairs. For times of elongation, see Table 1.

Conversion of Longitude Arc into Time, and vice versa.

Arc	Time	Time	Arc
1°	= 4 minutes	24 hours	= 360°
1′	= 4 seconds	1 hour	= 15°
1″	= 0.066.. second	1 minute	= 0° 15′
		1 second	= 0° 0′ 15″

For relation between time error and corresponding azimuth error, for Polaris, see "At culmination" and "At elongation," p. 288.

THE ENGINEER'S TRANSIT.

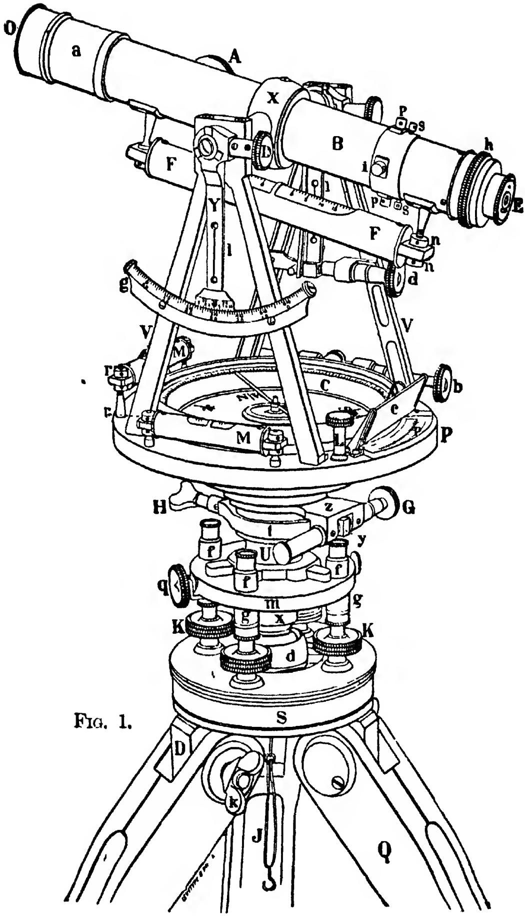

Fig. 1.

THE details of the transit, like those of the level, are differently arranged by diff makers, and to suit particular purposes. Without the **long bubble-tube** F F, Fig 1, under the telescope, and the **graduated arc** *g*, it is the **plain transit.** With these appendages, or rather with a graduated *circle* in place of the *arc*, it becomes virtually a **Complete Theodolite.**

B D D, Fig 2, is the **tripod-head.** The screw-threads at *v* receive the screw of a wooden tripod-head-cover when the instrument is out of use. S S A is the **lower parallel plate.** After the transit has been set very nearly over the center of a stake, the **shifting-plate,** *d d c c*, enables us, by slightly loosening the **levelling-screws** K, to shift the upper parts horizontally a trifle, and thus bring the plumb-bob exactly over the center with less trouble than by the older method of pushing one or two of the legs further into the ground, or spreading them more or less. The screws, K, are then tightened, thereby pushing upward the **upper parallel plate** *m m m x x*, and with it the half-ball *b*, thus pressing *c c* tightly up against the under side of S. The plumb-line passes

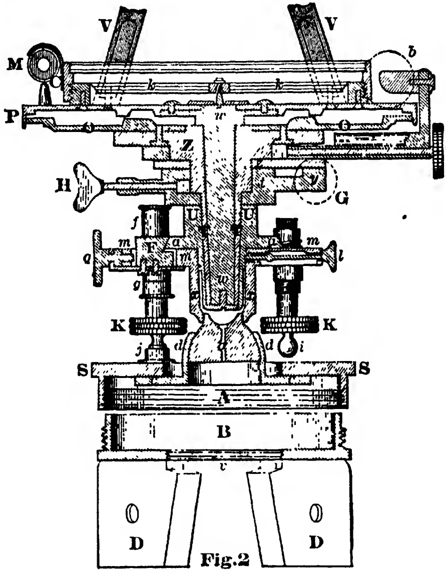

Fig.2

through the vert hole in *b*. Screw-caps, *f, g*, protect the levelling-screws from dust &c. The feet, *i*, of the screws, work in loose sockets, *j*, made flat at bottom to preserve S from being indented.

To set the upper parts upon the parallel plates. Place the lower end of U U in *x x*, holding the instrument so that the three blocks on *m m* (of which the one shown at F is movable) may enter the three corresponding

recesses in *a*, thus allowing *a* to bear fully on *m*, upon which the upper parts then rest. (The inner end of the spring-catch, *l*, in the meantime enters a groove around U, just below *a*, and prevents the upper parts from falling off, if the instrument is now carried over the shoulder.) Revolve the upper parts horizontally a trifle, in either direction, until they are stopped by the striking of a small lug on *a* against one of the blocks F. The recesses in *a* are now clear of the blocks. Tighten *q*, thereby pushing inward the movable block F, which clamps the bevelled flange *a* between it and the two fixed blocks on *m m*, and confines the spindle U to the fixed parallel plates. It remains so clamped while the instrument is being used.

To remove the upper parts from the parallel plates. Loosen *q*, bring the recesses in *a* opposite the blocks F. Hold back *l*, and lift the upper parts, which are then held together by the broad head of the screw inserted into the foot of the spindle *w*.

T T is the **outer revolving spindle,** cast in one with the **supporting-plate** Z Z, to which is fastened the **graduated limb** O O. The limb extends beyond the compass-box, and thus admits of larger graduations than would otherwise be obtainable. *w w* is the **inner revolving spindle.** At its top it has a broad flange, to which is fastened the vernier plate P. To the latter are fastened the compass-box C, the two bubble-tubes M M, the standards V V, supporting the telescope, &c. Each bubble-tube is supported and adjusted by four capstan head nuts, two at each end The bent strip, curving over the tube, protects the glass from accidental blows in swinging the telescope.

Control of motions of graduated limb O O **and vernier plate** P.—The tangent-screw G and a spiral spring (not shown) opposite to it are fixed to the graduated limb O O, and hold between them a projection *y* from the loose collar *t*, which is thus confined to the limb and made to travel with it. The clamp-screw H passes through the collar *t* and presses against the small lug shown at its inner end When H is tightened, this lug is pressed against the fixed spindle U U, to which the graduated limb is thus made fast. A slow motion may, however, still be given to the limb by means of the tangent-screw G

The motion of the vernier plate P over the graduated limb O O is similarly governed by the tangent-screw *b* and its spiral spring (not shown), fixed to the vernier plate P, and the clamp-screw *e*, which passes through the collar *z*, and presses against the small lug shown at its inner end.

There are two verniers One is shown at *p*, Fig 1. Both may be read, and their mean taken, when great accuracy is required. Ivory reflectors, *c*, facilitate their reading. Before the instrument is moved from one place to another, the **compass-needle,** *k*, Fig 2, should always be pressed up against the glass cover of the compass-box by means of the upright milled-head screw seen on the vernier-plate in Fig 1, just to the right of the nearest standard. The pivot-point is thus protected from injury.

R, Fig 1, is a ring with a clamp (the latter not shown) for holding the telescope in any required position. It is best to let the *eye*-end, E, of the telescope revolve *downward*, as otherwise the shade on O, if in use, may fall off. The tangent-screw, *d* moves a vert arm attached to R, and is thus used for slightly changing the elevation of the telescope. In the arm is a slit like that seen in the vernier-arm *l*. By means of the screw D, the movable vernier-arm Y may be clamped at any desired point on the vertical limb *g* When 0° of the vernier is placed at 90° on the arc *g*, and the index of the opposite arm is placed over a small notch on the horizontal brace (not seen in our figs) of the standards, the two slits will be opposite each other, and may be used for laying off offsets, &c, at right-angles to the line of sight.

One end, R, of the telescope axis rests in a movable box, under which is a screw By means of the screw, the box may be raised or lowered, and the axis thus adjusted for very slight derangements of the standards. For E, B, O, and A, see *Level*, p 306. *a* is a dust-guard for the object-slide.

Stadia Hairs. Immediately behind the capstan-screw, *p*, Fig 1, is seen a smaller one. This and a similar one on the opposite side of the telescope, work in a ring inside the telescope, and hold the ring in position. Across the ring are stretched two additional horizontal hairs, called stadia hairs, placed at such a distance apart, vertically, that they will subtend say 10 divisions of a graduated rod placed 100 ft from the instrument, 15 divisions at 150 ft, &c. They are thus used for measuring hor and sloping distances.

The long bubble-tube, F F, Fig 1, enables us to use the transit as a level although it is not so well adapted as the latter to this purpose.

To adjust a plain Transit.

When either a level or a transit is purchased, it is a good precaution (but one which the writer has never seen alluded to) to first screw the object-glass firmly home to its place; and then make a short continuous scratch upon the ring of the glass, and upon its slide; so as to be able to see at any time when at work, that the glass is always in the same position with regard to the slide. For if, after all the adjustments are completed, the position of the glass should become changed, (as it is apt to be if unscrewed, and afterward not screwed up to the same precise spot,) the adjustments may thereby become materially deranged; especially if the object-glass is eccentric, or not truly ground, which is often the case. Such scratches should be prepared by the maker. In making adjustments, as well as when using a transit or level, be careful that the eye-glass and object-glass are so drawn out that there shall be no parallax. The eye-glass must first be drawn out so as to obtain perfect distinctness of the cross-hairs; it must not be disturbed afterward; but the object-glass must be moved for different distances.

First, to ascertain that the bubble-tubes, M M, are placed parallel to the vernier-plate, *and that therefore when both bubbles are in the centers of their tubes the axis of the inst is vert.* By means of the four levelling-screws, K, bring both bubbles to the centers of their tubes in one position of the inst; then turn the upper parts of the inst *half-way* round. If the bubbles do not remain in the center, correct *half* the error by means of the two capstan-nuts *r r;* and the other half by the levelling-screws K. Repeat the trial until both bubbles remain in the center while the inst is being turned entirely around on its spindle.

Second, to see that the standards have suffered no derangement; that is, that they are of equal height and perpendicular to the vernier-plate, as they always are when they leave the maker's hands. Level the inst perfectly; then direct the intersection of the hairs to some point of a high object (as the top of a steeple) near by; clamp the inst by means of screws H and *e*, and lower the telescope until the intersection strikes some point of a low object. (If there is none such drive a stake or chain-pin, &c, in the line.) Then unclamp either H or *e*, and turn the upper parts of the inst half-way round; fix the intersection again upon the high point; clamp; lower the telescope to the low point. If the intersection still strikes the low point, the standards are in order. If not, correct *one-half* of the difference by means of the adjusting-block and screw at the end, R, of the telescope axis, Fig. 1, and repeat the trial *de novo*, resetting the stake or chain-pin at each trial. If the inst has no adjusting-block for the axis, it should be returned to the maker for correction of any derangement of the standards.

A transit may be used *for running straight lines*, even if the standards become slightly bent, by the process described at the end of the fourth adjustment.

Third, to see that the cross-hairs are truly vert and hor when the inst is level. When the telescope *inverts*, the cross-hairs are nearer the eye-end than when it shows objects erect. The maker takes care to place the cross-hairs at right-angles to each other in their ring, or diaphragm; and generally he so places the ring in the telescope, that when levelled, they shall be vert and hor. Sometimes, however, this is neglected; or the ring may by accident become turned a little. To be certain that one hair is vert, (in which case the other must, by construction, be hor,) after having adjusted the bubble-tubes, level the instrument carefully, and take sight with the telescope at a plumb-line, or other vert straight edge. If the vert hair coincides with this object, it is, *so far*, in adjustment; but if not, then loosen *slightly* only *two adjacent* screws of the four, *p p t t*, Fig 1; and with a knife, key, or other small instrument, tap very gently against the screw-heads, so as to turn the ring a little in the telescope; persevering until the hair becomes truly vertical. When this is done, tighten the screws. In the absence of a plumb-line, or vert straight edge, sight the cross-hair at a very small distinct point; and see if the hair still cuts that point, when the telescope is raised or lowered by revolving it on its axis

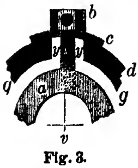

Fig. 3.

The mode of performing the foregoing will be readily understood from this Fig, which represents a section across the top part of the telescope, and at the cross-hairs. The hair-ring, or diaphragm, *a;* vert hair, *v;* telescope tube, *g;* ring outside of telescope tube, *d;* *b* is one of the four capstan-headed screws which hold the hair-ring, *a*, in its place, and also serve to adjust it. The lower ends of these screws work in the thickness of the hair-ring; so that when they are loosened somewhat, they do not lose their hold on the ring. Small loose

washers, c, are placed under the heads b of the screws. A space $y\,y$ is left around each screw where it passes through the telescope tube, to allow the screws and ring together to be moved a little sideways when the screws b are slightly loosened.

Fourth, to see that the vertical hair is in the line of collimation. Plant the tripod firmly upon the ground, as at a Level the inst; clamp it; and direct the vert hair by means of tangent-screw G (figs 1 and 2) upon some convenient object b, or if there is none such, drive a thin stake, or a chain-pin. Then revolving the telescope vert on its axis, observe some object, as c, where the vert hair now strikes, or if there is none, place a second pin. Unclamp the instrument by the clamp-screw H; and turn the whole upper part of it around until the vert hair again strikes b Clamp again; and again revolve the telescope vert on its axis. If the vert hair now strikes c, as it did before, it shows that c is really at o; and that b, a, c, *are in the same straight line*, and therefore this adjustment is in order If not, observe where it does strike, say at m, (the dist $a\,m$ being taken equal to $a\,c$,) and place a pin there also Measure $m\,c$; and place a pin at v, in the line $m\,c$, making $m\,v$ = one-fourth of $m\,c$. Also put a pin at o, half-way between m and c, or in range with a and b. By means of the two hor screws that move the ring carrying the cross-hairs, adjust the vert hair until it cuts v Now repeat the *entire* operation, and persevere until the telescope, after being directed to b, shall strike the same object o, *both times*, when revolved on its axis See whether the movement of the ring in this 4th adjustment has disturbed the verticality of the hair. If it has, repeat the 3d adjustment Then repeat the 4th, if necessary, and so on until both adjustments are found to be right at the same time Thus a straight line may be run, even if the hairs are out of adjustment; but with somewhat more trouble For at each station, as at a, two back-sights, and two fore-sights, $a\,c$ and $o\,m$, may be taken, as when making the adjustment, and the point o, half-way between c and m, will be in the straight line. The inst may then be moved to o, and the two back-sights be taken to a; and so on.

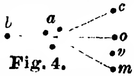

Fig. 4.

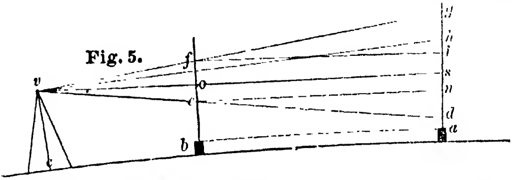
Angles measured by the transit, whether vert or hor, will evidently not be affected by the hairs being out of adjustment, provided either that the vert hair is truly vert, or that we use the *intersection* of the hairs when measuring.

The foregoing are all the adjustments needed, unless the transit is required for levelling, in which case the following one must be attended to:

Fig. 5.



To adjust the long bubble-tube, F F Fig 1, we first place the line of sight of the telescope hor, and then make the bubble-tube hor, so that the two are parallel Drive two pegs, a and b Fig 5, with their tops at precisely the same level (see Rem. p. 296) and at least about 100 ft apart; 300 or more will be better Plant the inst firmly, in range with them, as at c, making $b\,c$ an aliquot part of $a\,b$, and as short as will permit focusing on a rod at b. The inst need not be leveled Suppose the line of sight to cut e and d. Take the readings $b\,e$ and $a\,d$. Their diff is $b\,e - a\,d = a\,n - a\,d = d\,n$; and $a\,b : a\,c :: d\,n : d\,s$; s being the height of the target at a when the readings ($a\,s$, $b\,o$) on the two stakes are equal. $a\,s = a\,d + d\,s = a\,d + \frac{d\,n \times a\,c}{a\,b}$. If the reading on a *exceeds* that on b (as when the line of sight is $v\,f\,g$) the diff of readings is $= a\,g - b\,f = a\,g - a\,i = g\,i$; and $a\,s = a\,g - g\,s = a\,g - \frac{g\,i \times a\,c}{a\,b}$. Sight to s, bring the bubble to the cen of its tube by means of the two small nuts $n\,n$ at one end of the tube, Fig. 1, and assume that the telescope and tube are parallel.* The zeros of

* To correct for earth curvature and for atmosferic refraction (see p 153), make $s\,h$, ft, = 0 000 000 020 5 × ($a\,c$, ft)², and set target at h. (When $a\,c$ = 1,000 ft, $s\,h$ = 0.0205 ft.)

the vert circle, and of its vernier, may now be adjusted, if they require it, by loosening the vernier screws and then moving the vernier until the two coincide.

Rem. If no level is at hand for levelling the two pegs *a* and *b*, it may be done by the transit itself, thus. Carefully level the two short bubbles, by means of the levelling-screws K. Drive a peg *m*, from 100 to 300 feet from the instrument *o*. Then placing a target-rod on *m*, clamp the target tight at whatever height, as *e v*, the hor hair happens to cut it; it being of no importance whether the telescope is level or not; although it might as well be as nearly so as can conveniently be guessed at. Clamp the telescope in its position by the clamp-ring R, Fig. 1. Revolve the inst a considerable way round; say nearly or quite half way. Place another peg *n* *at precisely the same dist* from the instrument that *m* is; and continue to drive it until the hor hair cuts the target placed on it, and still kept clamped to the rod, at the same height as when it was on *m*. When this is done, the tops of the two pegs are on a level with each other, and are ready to be used as before directed.

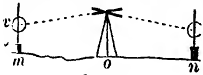


Fig. 6.

When a transit is intended to be used for surveying farms, &c, or for retracing lines of old surveys, it is very useful to set the compass so as to allow for the "variation" during the interval between the two surveys. For this purpose a **"variation-vernier"** is added to such transits; and also to the compass.

When the graduations of a transit are figured, or numbered, so as to read both ways from zero, thus, 
the vernier also is made double; that is, it also is graduated and numbered from its zero both ways. In this case, if the angle is measured from zero toward the right hand, the reading must be made from the right hand half of the vernier, and vice versa. If the figuring is single, or only in one direction, from zero to 360°, then only the single vernier is necessary, as the angles are then measured only in the direction that the figuring counts. Engineers differ in their preferences for various manners of figuring the graduations. The writer prefers from zero each way to 180°, with two double verniers.

To replace cross-hairs in a level, or transit. Take out the tube from the eye end of the telescope. Looking in, notice which side of the cross-hair diaphragm is turned toward the eye end. Then loosen the four screws which hold the diaphragm, so as to let the latter fall out of the telescope. Fasten on new hairs with beeswax, varnish, glue, or gum-arabic water, &c. This requires care. Then, to return the diaphragm to its place, press firmly into one of the screw-holes on the circumf of the diaphragm itself, the end of a piece of stick, long enough to reach easily into the telescope as far as to where the diaphragm belongs. By this stick, as a handle, insert the diaphragm edgewise to its place in the telescope and hold it there until two *opposite* screws are put in place and screwed. Then draw the stick out of the hole in the diaphragm; and with it turn the diaphragm until the same side presents itself toward the eye end as before; then put in the other two screws.

The so-called cross hairs are actually spider-web, so fine as to be barely visible to the naked eye.

To replace a spirit-level, or bubble-glass. Detach the level from the instrument; draw off its sliding ends; push out the broken glass vial, and the cement which held it; insert the new one, with the proper side up (the upper side is always marked with a file by the maker), wrapping some paper around its ends, if it fits loosely. Finally, put a little putty, or melted beeswax over the ends of the vial, to secure it against moving in its tube.

In purchasing instruments, especially when they are to be used far from a maker, it is advisable to provide extras of such parts as may be easily broken or lost; such as glass compass-covers, and needles; adjusting pins; level vials; magnifiers, &c.

Theodolite adjustments are performed like those of the level and transit.

1st. That of the cross-hairs; the same as in the level.

2d. The long bubble-tube of the telescope; also as in the level.

3d. The two short bubble-tubes; as in the transit.

4th. The vernier of the vert limb; as in the transit with a vert circle.

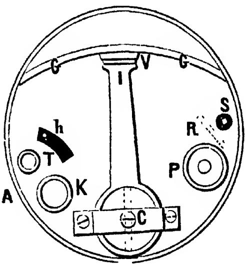
5th. To see that the vert hair travels vertically; as in the fourth adjustment of the transit. In some theodolites, no adjustment is provided for this; but in large ones it is provided for by screws under the feet of the standards.

Sometimes a second telescope is added; it is placed below the hor limb, and is

called a *watcher*. It has its own clamp, and tangent-screw. Its use is to ascertain whether the zero of that limb has moved during the measurement of hor angles. When, previously to beginning the measurement, the zero and upper telescope are directed toward the first object, point the lower telescope to any small distant object, and then clamp it. During the subsequent measurement, look through it, from time to time, to be sure that it still strikes that object; thus proving that no slipping has occurred.

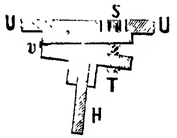
THE BOX OR POCKET SEXTANT.

THE portability of the pocket sextant, and the fact that it reads to single minutes, render it at times very useful to the engineer. By it, angles can be measured while in a boat, or on horseback; and in many situations which preclude the use of a transit. It is useful for obtaining latitudes, by aid of an artificial horizon. When closed, it resembles a cylindrical brass box, about 3 inches in diameter, and 1¼ inches deep. This box is in two parts: by unscrewing which, then inverting one part, and then screwing them together again, the lower part becomes a handle for holding the instrument. Looking down upon its top when thus arranged, we see, as in this figure, a movable arm I C, called the **index**, which turns on a center at C, and carries the vernier V at its other end. G G is the graduated arc or **limb.** It actually subtends about 73°, but is divided into about 146°. Its zero is at one end. Its graduations are not shown in the Fig.



Attached to the index is a small movable lens, (not shown in the figure,) likewise revolving around C, for reading the fine divisions of the limb. When measuring an angle, the index is moved by turning the milled-head P of a pinion, which works in a rack placed within the box. The eye is applied to a circular hole at the side of the box, near A. A small telescope, about 3 inches long, accompanies the instrument: but may generally be dispensed with. When so, the eye-hole at A should be partially closed by a slide which has a very small eye-hole in it; and which is moved by the pin *h*, moving in the curved slot. Another slide, at the side of the box, carries a dark glass for covering the eye-hole when observing the sun. When the telescope is used, it is fastened on by the milled-head screw T. The top part shown in our figure, can be separated from the cylindrical part, by removing 3 or 4 small screws around its edge; and the interior can then be examined, and cleaned if necessary. Like nautical, and other sextants, this one has two principal glasses, both of them mirrors. One, the **index-glass**, is attached to the underside of the index, at C; its upper edge being indicated by the two dotted lines. The other, the **horizon-glass**, (because, when measuring the vert angles of celestial bodies, it is directed toward the horizon,) is also within the box; the position of its upper edge being shown by the dotted lines at R. The horizon-glass is silvered only half-way down; so that one of the observed objects may be seen directly through its lower half, while the image of the other object is seen in the upper half, reflected from the index-glass. That the instrument may be in adjustment, ready for use, these two glasses must be at right angles to the plane of the instrument, that is, to the under side of the top of the box, to which they are attached; and must also be parallel to each other, when the zeros of the vernier and of the limb coincide. The index-glass is already permanently fixed by the maker, and requires no other adjustment. But the horizon-glass has two adjustments, which are made by a key like that of a watch, and having a milled-head K. It is screwed into the top of the box, so as to be always at hand for use. When needed, it is unscrewed. This key fits upon two small square-heads, (like that for

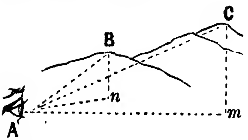
winding a watch;) one of which is shown at S; while the other is near it, but on the SIDE of the box. These squares are the heads of two small screws. If the horizon glass H should, as in this sketch, (where it is shown endwise,) not be at right angles to the top U U of the box, it is brought right by turning the square-head S of the screw S T; and if, after being so far rectified, it still is not parallel to the index-glass when the zeros coincide, it is moved a little backward or forward by the square head at the side.



To adjust a box sextant, bring the two zeros to coincide precisely; then look through the eye-hole, and the lower or unsilvered part of the horizon-glass, at some distant object. If the instrument is in adjustment, the object thus seen directly, will coincide precisely with its reflected image, seen at the same time, at the same spot. But if it is not in adjustment, the two will appear separated either hor or vert, or both, thus, * *; in which case apply the key K to the square-head S; and by turning it slightly in whichever direction may be necessary, *still looking at the object and its image*, bring the two into a hor position, or on a level with each other, thus, * *. Then apply the key to the square-head in the side of the box; and by turning it slightly, bring the two to coincide perfectly The instrument is then adjusted.

In some instruments, the hor glass has a *hinge* at *v*, to allow it play while being adjusted by the single screw S T; but others dispense with this hinge, and use *two* screws like S on top of the box, in addition to the one in the side.

If a sextant is used for measuring vert angles by means of an **artificial horizon**, the actual altitude will be but one-half of that read off on the limb; because we then read at once both the actual and the reflected angle. The great objection to the sextant for engineering purposes, is that it does not measure angles horizontally, as the transit does; unless when the observer, and the two objects happen to be in the same hor plane. Thus an observer with a sextant at A, if measuring the angle subtended by the mountain-peaks B and C, must hold the graduated plane of the sextant in the plane of A B C; and must actually measure the angle B A C: whereas what he wants is the hor angle *n* A *m*. This is greater than B A C, because the dists A *n* and A *m* are shorter than A B and A C. The transit gives the hor angle *n* A *m*, because its graduated plane is first fixed hor by the levelling-screws, and the subsequent measurement of the angle is not affected by his directing merely the line of sight upward, to any extent, in order to fix it upon B and C. For more on this subject; and for a method of partially obviating this objection to the sextant, see the note to Example 2, Case 4, of "Trigonometry."



The nautical sextant, used on ships, is constructed on the same principle as the box sextant; and its adjustments are very similar. In it, also, the index-glass is permanently fixed by the maker; and the horizon-glass has the two adjustments of the box sextant. It also has its dark glasses for looking at the sun; and a small sight-hole, to be used when the telescope is dispensed with.

THE COMPASS.

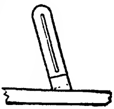
To adjust a Compass.

The first adjustment is that of the bubbles. Plant firmly; and level the instrument, in any position; that is, bring the bubbles to the centers of their tubes. Then turn the instrument half-way round If the bubbles then remain at the centers, they are in adjustment; but if not, correct *one-half* the diff in each bubble, by means of the adjusting-screws of the tubes. Level the instrument again; turn it half round; and if the bubbles still do not remain at the center, the adjusting-screws must be again moved a little, so as to rectify half the remaining diff. Gener

ally several trials must be thus made, until the bubbles will remain at the center while the compass is being turned entirely around.

Second adjustment. Level the compass, and then see that the needle is hor; and if not, make it so by means of the small piece of wire which is wrapped around it; sliding the wire toward the high end. A needle thus horizontally adjusted at one place, will not remain so if removed far north or south from that place. If carried to the north, the north end will dip down; and if to the south, the south end will do so. The sliding wire is intended to counteract this.

Third adjustment. This is always fixed right at first by the maker; that is, the sights, or slits for sighting through, are placed at right angles to the compass plate; so that when the latter is levelled by the bubbles, the sights are vert To test whether they are so, hang up a plumb-line; and having levelled the compass, take sight at the line, and see if the slits coincide with it. If one or both slits should prove to be out of plumb, as shown to an exaggerated extent in this sketch, it should be unscrewed from the compass, and a portion of its foot on the high side be filed or ground off, as per the dotted line; or as a temporary expedient, a small wedge may be placed under the low side, so as to raise it.



Fourth adjustment, to straighten the needle, if it should become bent The compass being levelled, and the needle hor, and loose on its pivot, see whether its two ends continue to point to exactly opposite graduations, (that is, graduations 180° apart,) while the compass is turned completely around. If it does, the needle is straight; and its pin is in the center of the graduated circle; but if it does not then one or both of these require adjusting. First level the compass. Then turn it until some graduation (say 90°) comes precisely to the north end of the needle. If the south end does not then point precisely to the opposite 90° division, lift off the needle, and bend the *pivot-point* until it does, remembering that every time said point is bent, the compass must be turned a hairsbreadth so as to keep the *north* end of the needle at its 90° mark. Then turn the compass half-way round, or until the *opposite* 90° mark comes precisely to the north end of the needle. Make a fine pencil mark where the *south* end of the needle now points. Then take off the needle, and bend it until its south end points *half-way between* its 90° mark and the pencil mark, while its north end is kept at 90° by moving the compass round a hairsbreadth. The needle will then be straight, and must not be altered in making the following adjustment, although it will not yet cut opposite degrees.

Fifth adjustment, of the pivot-pin. After being certain that the needle is straight, turn the compass around until a part is arrived at where the two ends of the needle happen to cut opposite degrees Then turn the compass *quarter way* around, or through 90°. If the needle then cuts opposite degrees, the pivot-point is already in adjustment, but if the needle does not so cut, bend the *pivot-point* until it does. Repeat, if necessary, until the needle cuts opposite degrees while being turned entirely around

Care and nicety of observation are necessary in making these adjustments properly; because the entire error to be rectified is, in itself, a minute quantity; and the novice is very apt to increase his trouble by not knowing how to use his **magnifier,** when looking at the end of the needle and the corresponding graduations. The magnifier must always be held with its *center directly over* the point to be examined; and it must be held parallel to the graduated circle. Otherwise annoying errors of several minutes will be made in a single observation; and the accumulation of two or three such errors, arising from a cause unknown to him, may compel him to abandon the adjustments in despair This suggestion applies also to the reading of angles taken by the transit, &c; although the errors are not then likely to be so great as in the case of the compass. In purchasing a magnifier for a compass, see that no part of it, as hinges, or rivets, are made of iron; for such would change the direction of the needle.

If the sight-slits of a compass are not fixed by the maker in line with the two opposite zeros, the engineer cannot remedy the defect. This can be ascertained by passing a piece of fine thread through the slits, and observing whether it stands precisely over the zeros.

MAGNETIC DECLINATION AND VARIATION

The Isogonic Chart opposit is reduced from a large chart for 1935 (latest up to 1937), publisht by the U S Coast & Geodetic Survey.

Ordinarily, the compass needle does not lie exactly in the meridian, *i e*, not in a true N & S line. Its angle of deviation from that line is called the **magnetic declination.** This is different in different places, and, at any given place, it varies from time to time.

Variations with Place

Apart from local attractions causd by iron or steel in buildings, track, machines, etc, in the soil or in mines, in ferruginus gravel, trap rock, etc, the average declination varies with markt regularity from place to place, starting from the "**agonic line**", or line of no declination, markt 0°, entering the country in Michigan, and leaving along the South Carolina-Georgia boundary. Along this agonic line, the needle normally points approx N & S; but at other places the north end of the needle tends away from the true north, toward that line. At places NE of the agonic line, the declination is west, and *vice versa;* and this declination increases with the dist from the agonic line, reaching at present 22° W in Maine, and 24° E in the state of Washington. **The heavy solid lines** on the chart, join points of equal declination, and are called **isogonic lines.** The figures scatterd over the chart (not along the margins or boundaries) give the approx local declinations, in degrees, where the changes of declination are so abrupt that it has been impracticable to indicate them by isogonic lines. See also notes at foot of chart.

Variation with Time

Secular Variation. At any given point, there may be a gradual change in the average declination. The **Annual Variation** is the amount of such secular variation each year, and is shown by **lines of equal annual change** which are dotted, markt 1′, 2′, etc. The **line of no annual change** (shown double and dotted, and markt 0′) appears in southern California, extends E and NE to the Great Lakes, and thence down the Atlantic Coast to the tip of Florida.

South of the line of no annual change, the average position of the compass needle is gradually shifting toward the east (*i e*, the E declination is increasing); and *vice versa.* It is impossible to predict with accuracy what the secular motion will be, for even a few years in advance.

Diurnal Variation. At any given place, the needle swings back and forth once daily, thru an arc sometimes as great as 12′ or 15′, reaching its extreme eastern position generally between 8 and 8:30 A M; its extreme western position generally betw 1:15 and 1:30 P M; and its mean position, or normal declination, generally betw 10 and 11:30 A M and betw 7 and 8 P M. The eastern extreme is reacht about half an hour earlier in summer and half an hour later in winter, and the western extreme about a quarter hour earlier in summer, and a quarter hour later in winter.

The total arc described between the eastern and western positions, or betw morning and afternoon, is called the **diurnal range.** At Philadelphia, this range varies from 5′ in midwinter to 12′ in midsummer; at Key West from 3′ to 8′; and at Los Angeles from 4′ to 9′ respectivly. In years of least sun-spot activity, the range is about 20% less, and in years of greatest sun-spot activity about 30% greater than the av range; but the diurnal variation is very irregular, especially in seasons of small diurnal range.

Other Variations. The average position of the needle varies slightly each month and also each year. Magnetic storms frequently cause temporary deflections of 15′ or more from the normal position of the needle. Machines moving nearby may cause variations of many degrees. Indeed, the compass should hardly be depended upon within close range of the works of civilization, tho it may be of value as a rough check on angle mesurements with the transit.

Electricity, either atmospheric, or excited by rubbing the glass cover of the compass box, sometimes gives trouble. It may be removed by touching the glass with the moist tongue or finger.

DEMAGNETIZATION.

The needle, if of *soft* metal, sometimes loses part of its magnetism, and consequently does not work well. It may be restored by simply drawing the north pole of a common magnet (either straight or horseshoe) about a dozen times, from the center to the end of the south half of the needle; and the south pole, in the same way, along the north half, pressing the magnet gently upon the needle. After each stroke, remove the magnet several inches from the needle, while bringing it back to the center for making another stroke. Each half of the needle in turn, while being thus operated on, should be held flat upon a smooth hard surface. Sluggish action of the needle is, however, more generally produced by the dulling or other injury of the point of the pivot Remagnetizing will throw the needle out of balance, which must be counteracted by the sliding wire

In order to prevent mistakes by reading sometimes from one end, and sometimes from the other end of the needle, it is best *always* to point the N of the compass-box toward the object whose bearing is to be taken; and to read off from the north end of the needle. This is also more accurate.

CONTOUR LINES.

A CONTOUR LINE is a curved hor one, every point in which represents the same level; thus each of the contour lines 88*c*, 91*c*, 94*c*, &c, Fig 1, indicates that every point in the ground through which it is traced is at the same level, and that that level or height is everywhere 88, 91, or 94 ft above a certain other level or height called *datum;* to which all others are referred.

Frequently the level of the starting point of a survey is taken as being 0, or zero, or datum; and if we are sure of meeting with no points lower than it, this answers every purpose. But if there is a probability of many lower points, it is better to assume the starting point to be so far above a certain supposed datum, that none of these lower points shall become minus quantities, or *below* said supposed datum or zero. The only object in this is to avoid the liability to error which arises when some of the levels are +, or plus; and some −, or minus. Hence we may assume the level of the starting point to be 10, 100, 1000, &c, ft above datum, according to circumstances.

The vert dists between each two contour lines are supposed to be equal; and in railroad surveys through well-known districts, where the engineer knows that his actual line of survey will not require to be much changed, the dist may be 1 or 2 ft only; and the lines need not be laid down for widths greater than 100 or 200 ft on each side of his center-stakes. But in regions of which the topography is comparatively unknown; and where consequently unexpected obstacles may occur which require the line to be materially changed for a considerable dist back, the observations should extend to greater widths; and for expedition the vertical dists apart may be increased to 3, 5, or even 10 ft, depending on the character of the country, &c. Also, when a survey is made for a topographical map of a State, or of a county, vert dists of 5 or 10 ft will generally suffice.

Let the line A B, Fig 1, starting from 0, represent three stations (S 1, S 2, S 3,) of the center line of a railroad survey; and let the numbers 100, 103, 101, 104, along that line denote the heights at the stakes above datum, as determined by levelling. Then the use of the contour lines is to show in the office what would be the effect of changing the surveyed center line A B, by moving any part of it

to the right or left hand.* Thus, if it should be moved 100 ft to the left, the starting point 0 would be on ground about 6 ft higher than at present; inasmuch as its level would then be about 106 ft above datum, instead of 100. Station 1 would be about 7 ft higher, or 110 ft instead of 103. Station 2 would be about 7 ft higher, or 108 ft instead of 101. If the line be thrown to the right, it will plainly be on lower ground.

The field observations for contour lines are sometimes made with the spirit-level; but more frequently by a slope-man, with a straight 12-ft graduated rod, and a slope instrument, or clinometer. At each station he lays his rod upon the ground, as

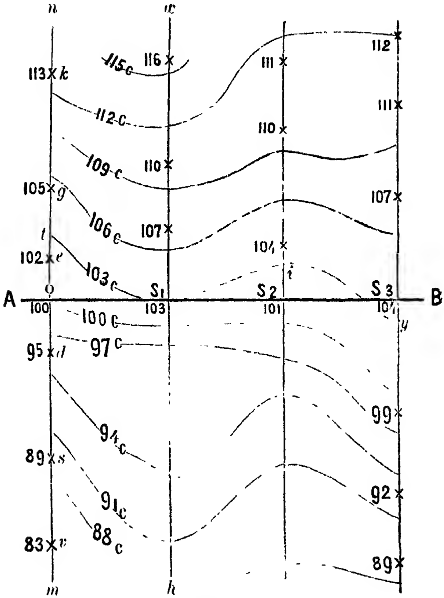

Fig. 1.

nearly at right angles to the center line A B as he can judge by eye; and placing the slope instrument upon it, he takes the angle of the slope of the ground to the nearest ¼ of a degree. He also observes how far beyond the rod the slope continues the same; and with the rod he measures the dist Then laying down the rod at that point also, he takes the next slope, and measures its length; and so on as far as may be judged necessary. His notes are entered in his field book as shown in Fig 2; the angles of the slopes being written above the lines, and their lengths below; and should be accompanied by such remarks as the locality suggests; such as woods rocks, marsh, sand, field, garden, across small run, &c, &c.

---

* In thus using the words right and left we are supposed to have our backs turned to the starting point of the survey. **In a river, the right bank** or shore is that which is on the right hand as we **descend** it, that is, in speaking of its right or left bank, we are supposed to have our backs turned towards its head, or origin; and so with a survey

It is not absolutely necessary to represent the slopes roughly in the field-book, as in Fig 2; for by using the sign + to signify "up;" —"down;" and = "level," the slopes may be written in a straight line, as in Fig 2½.

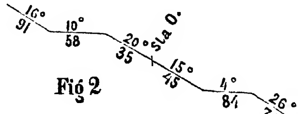

Fig 2

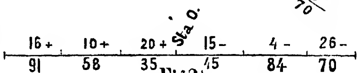

Fig 2½

The notes having been taken, the preparation of the contour lines by means of them, is of course office-work; and is usually done at the same time as the drawing of the map, &c. The field observations at each station are then separately drawn by protractor and scale as shown in Fig 3 for the starting point O. The scale should not be less than about $\frac{1}{12}$ inch to a ft, if anything like accuracy is aimed at. Suppose that at said station the slopes to the right, taken in their order, are, as in Fig 2, 15°, 4°, and 26°; and those to the left, 20°, 10°, and 16°; and their lengths as in the same Fig. Draw a hor line *h o*, Fig 3; and consider the center of it to be the station-stake. From this point as a center, lay off these angles with a protractor, as shown on the arcs in Fig 3. Then beginning say on the right hand, with a parallel ruler draw the first dist *a c*, at its proper slope of 15°; and of its proper length, 45 ft, by scale. Then the same with *c y* and *y t*. Do the same with those on the left hand. We then have a *cross-section* of the ground at Sta O Then on the map, as in Fig 1, draw a line as *m n*, or *h w*, at right angles to the line of road, and passing through the station-stake. On this line lay down the *hor* dists *a d*, *d s*, *s v*, *a e*, *e g*, *g k*, marking them with a small star, as is done and lettered in Fig 1, at Sta O.

When extreme accuracy is pretended to, these hor dists must be found by measure on Fig 3; but as a general rule it will be near enough, when the slopes do not exceed 10°, to assume them to be the same as the sloping dists measured in the field. Next ascertain how high each of the points *c y t l n i* is above datum Thus, measure by scale the vert dist *d c* Suppose it is found to be 5 ft; or in other words, that *c* is 5 ft *below* station-stake O. Then since the level at stake O is 100 ft above datum, that at *c* must be 5 ft *less*, or 100 — 5 = 95 ft above datum; which may be marked in light lead-pencil figures on the map, as at *d*, Fig 1. Next for the point *y*, suppose we find *s y* to be 11 ft, or *y* to be 11 ft *below* stake O; then its height above datum must be 100 — 11 = 89: which also write in pencil, as at *s* Proceed in the same way with *t*. Next going to the left hand of the station-stake, we find *e l* to be say 2 ft; but *l* is *above* the level of the station-stake, therefore its height above datum is

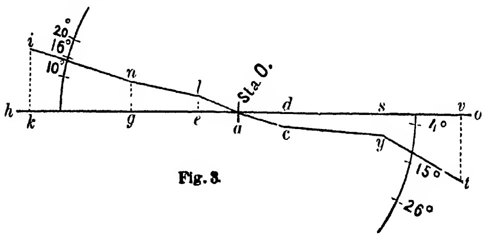

Fig. 3.

100 + 2 = 102 ft, as figured at *e* on the map. Let *n g* be 5 ft; then is *n*, 100 + 5 = 105 ft above datum, as marked at *g*; and so on at each station. When this has been done at several stations, we may draw in the contour lines of that portion by hand thus: Suppose they are to represent vert heights of 3 ft. Beginning at Station O (of which the height above datum is 100 ft) to lay down a contour line 103 ft above datum, we see at once that the height of 103 ft must be at *l*, or at ⅓ the dist from *e* to *g*. Make a light lead-pencil dot at *t*; and then go to the next Station 1. Here we see that the height of 103 ft coincides with the station-stake itself; place a dot there, and go to Sta 2. The level at this stake is 101; therefore the contour for 103

it must evidently be 2 ft higher, or at *i*, ⅔ of the dist from Sta 2 to +104; therefore make a dot at *i*. Then go to Sta 3. Here the level being 104 above datum, the contour of 103 must be at *y*, or $\frac{1}{5}$ of the dist from Sta 3 to +99; put a dot at *y*. Finally draw by hand a curving line through *t*, S1, *i*, and *y*; and the contour line of 103 ft is done. All the others are prepared in the same way, one by one. The level of each must be figured upon it at short intervals along the map, as at 103 *c*, 106 *c*, &c.

Or, instead of first placing the + points on the map, to denote the slope dists actually measured upon the ground, we may at once, and with less trouble, find and show those only which represent the points *t*, S 1, *i*, *y*, &c, of the contours themselves. Thus, say that at any given station-stake, Fig 4, the level is 104; that the cross-section *c s* of the ground has been prepared as before; and that we want the hor dists from the stake, to contour lines for 94, 97, 100 ft, &c, 3 ft apart vert.

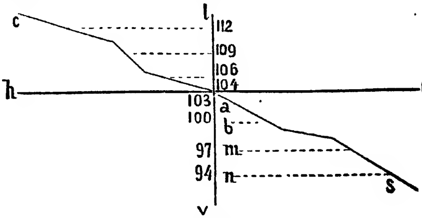

Fig. 4.

Draw a vert line *v l*, through the station-stake, and on it by scale mark levels of 94, 97, 100, &c. ft. This is readily done, inasmuch as we have the level 104 of the stake already given. Through these levels draw the hor lines *a*, *b*, *m*, *n*, &c. to the ground-slopes. Then these lines, measured by the scale, plainly give the required dists.

When the ground is very irregular transversely, the cross-sections must be taken in the field nearer together than 100 ft. The preparation of contour lines will be greatly facilitated by the use of paper ruled into small squares of not less than about $\frac{1}{12}$ inch to a side, for drawing the cross-sections upon.

When the ground is very steep, it is usual to shade such portions of the map to represent hill-side. The closer together the contours come, the steeper of course is the ground between them; and the shading should be proportionally darker at such portions. But for *working* maps it is best to omit the shading.

In surveys of wide districts, the transit instrument with a graduated vertical circle or arc, *g*, p 291, is used for measuring the angles of slope, instead of the common slope-instrument.

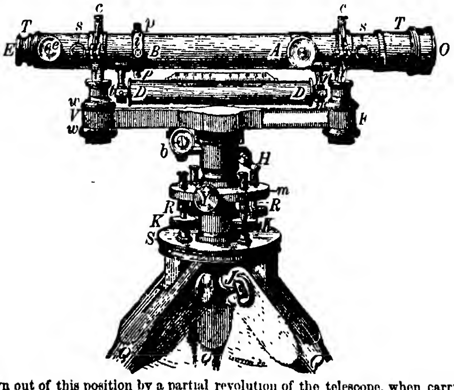
In many cases, notes similar to the following will serve the purpose of contour lines on railroad surveys.

Sta 60.. .	....— 3 1 R	+ 2 1 L.
61... ..	.... + 2. 2 R.	— 1 3 L.
62	..... = 1. R.	+ 4. 2 L.
63	"	"

Which means that at station 60, the slope of the ground on the right, as nearly as he can judge by eye, or by his hand-level, is about 3 ft downward for 1 chain, or 100 ft; and on the left, about 2 ft upward in 1 chain. At 61, 2 ft up, in 2 chains to the right; and 1 ft down in 3 chains to the left. At 62, level for 1 chain to the right, and ascending 4 ft in 2 chains to the left. At 63, the same as at 62. At some spots it will be well to add a sketch of a cross-section, like Fig 2; only, instead of the angles, use ft of rise or fall, to indicate the slopes, as judged by eye, or by a hand-level. By this method, the result at every station will be somewhat in error but these small errors will balance each other so nearly that the total may be regarded as sufficiently correct for all the purposes of a preliminary estimate of the cost of a road. When the final stakes for guiding the workmen are placed the slopes should be carefully taken, in order to calculate the quantity of excavation accurately for payment.

THE LEVEL.

ALTHOUGH the levels of different makers vary somewhat in their details, still their principal parts will be understood from the following figure. The telescope T T rests upon two supports YY, called Ys, out of which it can be lifted, first removing the pins *s s* which confine the semicircular *clips c c*, and then opening the clips. The pins should be tied to the Ys, by pieces of string, to prevent their being lost. The *slide* of the *object-glass* O, is moved backward or forward by a rack and pinion, by means of the milled head A. The slide of the *eye-glass* E, is moved in the same way by the milled head *e*. A cylindrical tube of brass, called a *shade*, is usually furnished with each level. It is intended to be slid on to the object-end O of the telescope, to prevent the glare of the sun upon the object-glass, when the sun is low. At B is an outer ring encircling the telescope, and carrying 4 small capstan-headed screws; two of which, *p p*, are at top and bottom; while the other two, of which *i* is one, are at the sides, and at right angles to *p p*. Inside of this outer ring is another, inside of the telescope, and which has stretched across it two spider-webs, usually called the CROSS-HAIRS. These are much finer than they appear to be, being considerably magnified. They are at right angles to each other; and, in levelling, one is kept vert, and the other hor. They are liable at times to be



thrown out of this position by a partial revolution of the telescope, when carrying the level, or when setting the tripod down suddenly upon the ground; but since, in levelling, the *intersection* of the hairs is directed to the target-rod, this derangement does not affect the accuracy of the work. Still it is well to keep them nearly vert and hor, by keeping the BUBBLE-TUBE D D as nearly directly over the bar V F as can be judged by eye. This enables the leveller to see that the rod-man holds his rod nearly vert, which is absolutely essential for correct levelling. If perfect verticality is desired, as is sometimes the case, when staking out work, it may be obtained (*if the instrument is in perfect adjustment, and levelled*) by sighting at a plumb-line, or other vert object, and then turning the telescope a little in its Ys, so as to bring the hair to correspond. When this is done, a short continuous scratch may be made on the telescope and Y, to save that trouble in future.

The small holes around the heads of the 4 small capstan-screws *p*, *i*, just referred to, are for admitting the end of a small steel pin, or lever, for turning them. If first the upper screw *p* be loosened and then the lower one tightened, the interior ring will be lowered, and the horizontal hair with it. But on looking through the tele-

scope they will *appear* to be raised. If first the lower one be loosened, and the upper one tightened, the hor hair will be actually raised, but apparently lowered. This is because the glasses in the eye-piece E reverse the apparent position of objects *inside* of the telescope; which effect is obviated, as regards *exterior* objects, by means of the object-glass O. This must be remembered when adjusting the cross-hairs; for if a hair appears to strike too high, it must be raised still higher; if it appears to be already too far to the right or left, it must be actually moved still more in the same direction.

This remark, however, does not apply to telescopes which make objects appear inverted.

There is no danger of injuring the hairs by these motions, inasmuch as the four screws act against the ring only, and do not come in contact with the hairs themselves

Under the telescope is the BUBBLE-TUBE D D One end of this tube can be raised or lowered slightly by means of the two capstan-headed nuts *n n*, one of which must be loosened before the other is tightened. On top of the bubble-tube are scratches for showing when the bubble is central in the tube. Frequently these scratches, or marks, are made on a strip of brass placed above the tube, as in our fig There are several of them, to allow for the lengthening or shortening of the bubble by changes of temperature. At the other end of the bubble-tube are two small capstan-screws, placed on opposite sides horizontally The circular head of one of them is shown near *t*. By means of these two screws, that end of the tube can be slightly moved hor, or to right or left Under the bubble-tube is the BAR V F; at one end of which, as at V, are two large capstan-nuts *w w*, which operate upon a stout interior screw which forms a prolongation of the Y. The holes in these nuts are larger than the others, as they require a larger lever for turning them. If the lower nut is loosened and the upper one tightened, the Y above is raised; and that end of the telescope becomes farther removed from the bar; and vice versa. Some makers place a similar screw and nuts under both Ys; while others dispense with the nuts entirely, and substitute beneath one end of the bar a large circular milled head, to be turned by the fingers This, however, is exposed to accidental alteration, which should be avoided.

When the portions above *m* are put upon *m*, and fastened by the screw **Y**, all the upper part may be swung round hor, in either direction, by loosening the **clamp-screw** H; or such motion may be prevented by tightening that screw. It frequently happens, after the telescope has been sighted very nearly upon an object, and then clamped by H, that we wish to bring the cross-hairs to coincide more precisely with the object than we can readily do by turning the telescope *by hand;* and in this case we use the **tangent-screw** *b*, by means of which a slight but steady motion may be given after the instrument is clamped. For fuller remarks on the clamp and tangent-screws, see "Transit."

The **parallel plates** *m* and S are operated by four **levelling-screws;** three of which are seen in the figure, at K K. The screws work in sockets R; which, as well as the screws, extend above the upper plate. When the instrument is placed on the ground for levelling, it is well to set it so that the lower parallel plate S shall be as nearly horizontal as can be roughly judged by eye; in order to avoid much turning of the levelling screws K K in making the upper plate *m* hor. The lower plate S, and the brass parts below it, are together called the **tripod-head;** and, in connection with three wooden legs Q Q Q, constitute the tripod. In the figure are seen the heads of wing-nuts J which confine the legs to the tripod-head. Under the center of the tripod-head should always be placed a small ring, from which a plumb-bob may be suspended. This is not needed in ordinary levelling, but becomes useful when ranging center-stakes, &c.

To adjust a Level.

This is a quite simple operation, but requires a little patience. Be careful to avoid *straining* any of the screws. The large Y nuts *w w* sometimes require some force to *start* them; but it should be applied by pressure, and not by blows. Before beginning to adjust, attend to the object-glass, as directed in the first sentence under "To adjust a plain transit."

Three adjustments are necessary: *and must be made in the following order:*

First, that of the cross-hairs; to secure that their intersection shall continue to strike the same point of a distant object, while the telescope is being turned round a complete revolution in its Ys. This is called adjusting the **line of collimation,** or sometimes, the *line of sight;* but it is not strictly the line of sight until all the adjustments are finished; for until then, the line of collimation will not serve for taking levelling sights. **If cross-hairs break.** see p 296.

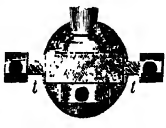
Second, that of the bubble-tube D D, to place it parallel to the line

of collimation. previously adjusted; so that when the bubble stands at the centre of its tube, indicating that it is level, we know that our sight through the telescope is hor. To replace **broken bubble tube.** see p 296

Third, that of the Ys, by which the telescope and bubble-tube are supported; so that the bubble-tube, and line of sight, shall be perp to the vert axis of the instrument; so as to *remain* hor while the telescope is pointed to objects in diff directions, as when taking back and fore sights.

To make the first adjustment, or that of the cross-hairs, plant the tripod *firmly* upon the ground. In this adjustment it is not necessary to level the instrument. Open the clips of the Ys; unclamp; draw out the eye-glass E, until the cross-hairs are seen *perfectly clear;* sight the telescope toward some clear distant point of an object; or still better, toward some straight line, whether vert or not. Move the object-glass O, by means of the milled head A, so that the object shall be clearly seen, **without parallax,** that is, without any apparent dancing about of the cross-hairs, if the eye is moved a little up or down or sideways. To secure this, the object-glass alone is moved to suit different distances; the eye-glass is not to be changed after it is once properly fixed upon the cross-hairs. The neglect of parallax is a source of frequent errors in levelling. Clamp; and, by means of the tangent-screw *b*, bring either one of the cross-hairs to coincide *precisely* with the object. Then gently, and without jarring, revolve the telescope half-way round in its Ys. When this is done, if the hair still coincides precisely with the object, it is in adjustment; and we proceed to try the other hair. But if it does not coincide, then by means of the 4 screws *p, t*, move the ring which carries the hairs, so as to rectify, as nearly as can be judged by eye, only *one-half* of the error; remembering that the ring must be moved in the direction opposite to what *appears* to be the right one; unless the telescope is an inverting one. Then turn the telescope back again to its former position; and again by the tangent-screw bring the cross-hair to coincide with the object. Then again turn the telescope half-way round as before. The hair will now be found to be more nearly in its right place, but, in all probability, not precisely so, inasmuch as it is difficult to estimate one-half the error accurately by eye. Therefore a little more alteration of the ring must be made; and it may be necessary to repeat the operation several times, before the adjustment is perfect. Afterward treat the other hair in precisely the same manner. When both are adjusted, their intersection will strike the same precise spot while the telescope is being turned *entirely* round in its Ys. This must be tried before the adjustment can be pronounced perfect; because at times the adjustment of the second hair slightly deranges that of the first one; especially if both were much *out* in the beginning.

To make the second adjustment, or to place the bubble-tube parallel to the line of collimation. This consists of two distinct adjustments, one vert. and one hor. The first of these is effected by means of the two nuts *n n* on the vert screw at one end of the tube; and the second by the two hor screws at the other end, *t*, of the tube. Looking at the bubble-tube endwise, from *t* in the foregoing Fig, its two hor adjusting-screws *t t* are seen as in this sketch. The larger capstan-headed nut *below*, has nothing to do with the adjustments; it merely holds the end of the tube in its place.



To make the vert adjustment of the bubble-tube, by means of the two nuts *n n*. Place the telescope over a diagonal pair of the levelling-screws K K, and clamp it there. Open the clips of the Ys; and by means of the levelling-screws bring the bubble to the center of its tube. Lift the telescope gently out of the Ys, turn it end for end, and put it back again in its reversed position. This being done, if the bubble still remains at the center of its tube, this adjustment is in order; but if it moves toward one end, that end is too high, and must be lowered; or else the other end must be raised. First, correct *half* the error by means of the levelling-screws K K, and then the remaining half by means of the two small capstan-headed nuts *n n*. To *raise* the end *n*, first loosen the upper nut and then tighten the lower one, to do which, turn each nut so that the *near* side moves toward your *right*. To *lower* it, first loosen the lower nut, then tighten the upper one, moving the *near* side of each nut toward your *left*. Having thus brought the bubble to the middle again, again lift the telescope out of its Ys; turn it end for end, and replace it. The bubble will now settle nearer the center than it did before, but will probably require still further adjustment. If so, correct *half* the remaining error by the levelling-screws, and half by the nuts, as before; and so continue to repeat the operation until the bubble remains at the center in both positions. For another method, see "To adjust the long bubble-tube," p 295.

Horizontal adjustment of bubble tube; to see that its axis is in the same plane with that of the telescope, as it usually is in new instruments. It is not easily de

ranged, except by blows. Have the bubble-tube, as nearly as may be, directly under the telescope, or over the center of the bar V F. Bring the telescope over two of the levelling-screws K K; clamp it there; center the bubble with said screws; turn the telescope in its Ys, say about ¼ inch, bringing the bubble-tube out from over the center of the bar, first on one side, then on the other. If the bubble stays centered while so swung out, this adjustment is correct. If it runs toward *opposite* ends of its tube when swung out on opposite sides of the center, move the end *t* of the tube by the two horizontal screws *t t* until the bubble stays centered when the tube is swung out on either side. If the bubble runs toward the *same* end of its tube *on both sides*, the tube is not truly cylindrical, but slightly conical,* so that if the telescope is turned in its Ys the bubble will leave the center, even when the horizontal adjustment is correct. It is known to be correct, in such tubes, if the bubble runs *the same distance* from the center when swung out the same distance on each side.

Having made the horizontal adjustment, turn the telescope back in its Ys until the bubble-tube is over the bar. Repeat the *vertical* adjustment (p 308), which may have become deranged in making this horizontal one. Persevere until both adjustments are found to be correct at the same time.

To make the third adjustment, or to adjust the heights of the Ys, so as to make the line of collimation parallel to the bar V F, or perp to the vert axis of the instrument. The other adjustments being made, fasten down the clips of the Ys. Make the instrument nearly level by means of all four of the levelling-screws K. Place the telescope over two of the levelling-screws which stand diagonally, and leave it there unclamped. Then bring the bubble to the center of its tube, by the two levelling-screws. Swing the upper part of the instrument half-way around, so that the telescope shall again stand over the same two screws; but end for end. This done, if the bubble leaves the center, bring it *half-way* back by the large capstan nuts *w*, *w*; and the other half by the two levelling-screws. Remember that to raise the Y, and the end of the bubble over *w*, *w*, the lower *w* must be loosened; and the upper one tightened; and vice versa. Now place the telescope over the other diagonal pair of levelling-screws; and repeat the whole operation with them. Having completed it, again try with the first pair; and so keep on until the bubble remains at the center of its tube, in every position of the telescope.

Correct levelling may be performed even if all the foregoing adjustments are out of order; provided each fore-sight be taken *at precisely the same distance from the instrument as the back-sight is*. But a good leveller will keep his instrument always in adjustment; and will test the adjustments at least once a day when at work. As much, however, depends upon the rodman, or target-man, as upon the leveller. A rodman who is careless about holding the rod vert, or about reading the sights correctly should be discharged without mercy.

The levelling-screws in many instruments become very hard to turn if dirty. Clean with water and a tooth-brush. Use no oil on field instruments.

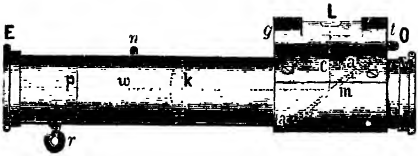
Forms for level note-books. When the distance is short, so as not to require two sets of books, the following is perhaps as good as any.

No. of Station.	Back sights	Fore sights.	Diff.	Level.	Grade.	Cut.	Fill.

But on public works generally the original field-books have only the first five cols After the grades have been determined by means of the profile drawn from these, the results are placed in another book, which has only the first col and the last four. In both cases, the right-hand page is reserved for memoranda. The writer considers it best, both with the level and with the transit, to consider the term "STATION" to apply to the whole dist between two consecutive stakes; and that its number shall be that written on the last stake. Thus, with the transit, Station 6 means the dist from stake 5 to stake 6; that it has a bearing or course of so and so; and its length is so and so. And with the level, Station 6 also means the dist from stake 5 to stake 6; the back-sight for that dist being taken at stake 5, and the fore-sight on stake 6; and that the level, grade, cut, or fill is that at stake 6. The starting-point of the survey, whether a stake, or any thing else, we call and mark simply 0.

* This defect can be remedied only by removing the tube and inserting a correctly-shaped one, and this is best done by an instrument-maker; but correct work can be done in spite of it, thus: Make all the adjustments as nearly correct as possible. Level the instrument. By turning the telescope in its Ys, make the vertical hair coincide with a plumb-line or other vertical line, and make a short continuous knife-scratch on the collar nearest the object-glass, and on the adjoining Y. Lift the telescope out of its Ys, turn it end for end, replace it in its Ys; again bring the upright hair vertical, and make on the other Y a scratch coinciding with that on the collar. Then, in levelling or in adjusting, always see that the scratch on the collar coincides with that on the adjoining Y when the bubble-tube is under the telescope.

THE HAND-LEVEL.



THIS very useful little instrument, as arranged by Professor Locke, of Cincinnati, is but about five or six inches long. Simply holding it in one hand, and looking through it in any direction, we can ascertain at once, approximately, what objects are at the same level with the eye. E is the eye end; and O the object end. L is a small level, enclosed in a kind of brass boxing t g, the bottom of which is open with a corresponding opening under it, through the top of the main tube E O. Immediately at the bottom of the small level L, is a cross-wire, stretched across said opening, and carried by a small plate, which, for adjusting the wire, can be pushed backward a trifle by tightening the screw t, or pushed forward by a small spring within the boxing, near g, when the screw t is loosened. At m is a small semicircular mirror a a, silvered on the back m. This is placed at an angle of 45°, and occupies one-half the width of the tube E O. Through the forementioned openings, the images of the cross-wire and of the level bubble are reflected down on the unsilvered face a a of the mirror, and thence to the eye, as shown by the single dotted lines c and w; and when the instrument is adjusted and held level, the wire will appear to be at the center of the bubble. At k is one half of a plano-convex lens, at the inner end of a short tube k p, which may be moved backward or forward by a pin n, projecting through a short slit in the main tube. By this means the image of the cross-wire is rendered distinct, and the half lens must be moved until, when viewing an object, the wire shall show no parallax; but appear steady against the object when the eye is slightly moved up or down. At each end of the tube E O is a circular piece of plain glass for excluding dust.

To adjust the hand-level, first fix two precisely level marks, say from 50 feet to 100 yards apart. This being done, rest the instrument against one of the level marks, and take sight at the other. If, then, the wire does not appear to be precisely at the center of the bubble, move it slightly backward or forward, as the case may be, by the screw t, until it does so appear. The two level marks may be fixed by means of the hand-level itself, even if it is entirely out of adjustment, thus. First, by the pin n arrange the half lens k, so as to show the wire distinctly and without parallax. Then holding the level steadily, at any selected object, as a, so that the wire appears to cut the center

of the bubble, see where it cuts any other convenient object, as b. Then go to b and from it, in like manner, sight back toward a. If the instrument is in adjustment, the wire will cut a; but if not, it will strike either above it or below it, as at c. In either case, make a mark m, half-way between c and a. Then b and m will be the two level marks required. With care, these adjustments, when once made, will remain in order for years. The instrument generally has a small ring r, for hanging it around the neck: it is not adapted to very accurate work, but admirably so for exploring a route. The height of a bare hill can be found by beginning at the foot, and sighting ahead at any little chance object which the cross-wire may strike, as a pebble, twig, &c; then going forward, stand at that object, and fix the wire on another one still farther on, and so to the top. At each observation we plainly rise a height equal to that of the eye, say 5¼ feet, or whatever it may be. Whether going up or down it, if the hill is covered with grass, bushes, &c. a target rod must be used for the fore-sights; and the constant height of the eye may be regarded as the back-sight at each station. An attachment may be made for screwing the level to a small ball and socket on top of a cane, or of a longer stick, for occasional use, when rather more accuracy is desired.

ranged, except by blows. Have the bubble-tube, as nearly as may be, directly under the telescope, or over the center of the bar V F. Bring the telescope over two of the levelling-screws K K; clamp it there; center the bubble with said screws; turn the telescope in its Ys, say about ¼ inch, bringing the bubble-tube out from over the center of the bar, first on one side, then on the other. If the bubble stays centered while so swung out, this adjustment is correct. If it runs toward *opposite* ends of its tube when swung out on opposite sides of the center, move the end *t* of the tube by the two horizontal screws *t t* until the bubble stays centered when the tube is swung out on either side. If the bubble runs toward the *same* end of its tube *on both sides*, the tube is not truly cylindrical, but slightly conical,* so that if the telescope is turned in its Ys the bubble will leave the center, even when the horizontal adjustment is correct. It is known to be correct, in such tubes, if the bubble runs *the same distance* from the center when swung out the same distance on each side.

Having made the horizontal adjustment, turn the telescope back in its Ys until the bubble-tube is over the bar. Repeat the *vertical* adjustment (p 308), which may have become deranged in making this horizontal one. Persevere until both adjustments are found to be correct at the same time.

To make the third adjustment, or to adjust the heights of the Ys, so as to make the line of collimation parallel to the bar V F, or perp to the vert axis of the instrument. The other adjustments being made, fasten down the clips of the Ys. Make the instrument nearly level by means of all four of the levelling-screws K. Place the telescope over two of the levelling-screws which stand diagonally, and leave it there unclamped. Then bring the bubble to the center of its tube, by the two levelling-screws. Swing the upper part of the instrument half-way around, so that the telescope shall again stand over the same two screws; but end for end. This done, if the bubble leaves the center, bring it *half-way* back by the large capstan nuts *w*, *w*; and the other half by the two levelling-screws. Remember that to raise the Y, and the end of the bubble over *w*, *w*, the lower *w* must be loosened; and the upper one tightened; and vice versa. Now place the telescope over the other diagonal pair of levelling-screws; and repeat the whole operation with them. Having completed it, again try with the first pair; and so keep on until the bubble remains at the center of its tube, in every position of the telescope.

Correct levelling may be performed even if all the foregoing adjustments are out of order; provided each fore-sight be taken *at precisely the same distance from the instrument as the back-sight is*. But a good leveller will keep his instrument always in adjustment; and will test the adjustments at least once a day when at work. As much, however, depends upon the rodman, or target-man, as upon the leveller. A rodman who is careless about holding the rod vert, or about reading the sights correctly should be discharged without mercy.

The levelling-screws in many instruments become very hard to turn if dirty. Clean with water and a tooth-brush. Use no oil on field instruments.

Forms for level note-books. When the distance is short, so as not to require two sets of books, the following is perhaps as good as any.

No. of Station.	Back sights	Fore sights.	Diff.	Level.	Grade.	Cut.	Fill.

But on public works generally the original field-books have only the first five cols After the grades have been determined by means of the profile drawn from these, the results are placed in another book, which has only the first col and the last four. In both cases, the right-hand page is reserved for memoranda. The writer considers it best, both with the level and with the transit, to consider the term "STATION" to apply to the whole dist between two consecutive stakes; and that its number shall be that written on the last stake. Thus, with the transit, Station 6 means the dist from stake 5 to stake 6; that it has a bearing or course of so and so; and its length is so and so. And with the level, Station 6 also means the dist from stake 5 to stake 6; the back-sight for that dist being taken at stake 5, and the fore-sight on stake 6; and that the level, grade, cut, or fill is that at stake 6. The starting-point of the survey, whether a stake, or any thing else, we call and mark simply 0.

* This defect can be remedied only by removing the tube and inserting a correctly-shaped one, and this is best done by an instrument-maker; but correct work can be done in spite of it, thus: Make all the adjustments as nearly correct as possible. Level the instrument. By turning the telescope in its Ys, make the vertical hair coincide with a plumb-line or other vertical line, and make a short continuous knife-scratch on the collar nearest the object-glass, and on the adjoining Y. Lift the telescope out of its Ys, turn it end for end, replace it in its Ys; again bring the upright hair vertical, and make on the other Y a scratch coinciding with that on the collar. Then, in levelling or in adjusting, always see that the scratch on the collar coincides with that on the adjoining Y when the bubble-tube is under the telescope.

LEVELLING BY THE BAROMETER.

1. Many circumstances combine to render the results of this kind of levelling unreliable where great accuracy is required. This fact was most conclusively proved by the observations made by Captain T. J. Cram, of the U. S. Coast Survey. See Report of U. S. C. S., vol. for 1854 It is difficult to read off from an aneroid (the kind of barom generally employed for engineering purposes) to within from two to five or six ft, depending on its size The moisture or dryness of the air affects the results; also winds, the vicinity of mountains, and the daily atmospheric tides, which cause incessant and irregular fluctuations in the barom. A barom hanging quietly in a room will often vary $\frac{1}{10}$ of an inch within a few hours, corresponding to a diff of elevation of nearly 100 ft No formula can possibly be devised that shall embrace these sources of error. The variations dependent upon temperature, latitude, &c, are in some measure provided for; so that with *very delicate* instruments, a *skilful* observer may measure the diff of altitude of two points close together, such as the bottom and top of a steeple, with a tolerable confidence that he is within two or three feet of the truth. But if as short an interval as even a few hours elapses between his two observations, such changes may occur in the condition of the atmosphere that he *may* make the top of the steeple to be lower than its bottom; or at least, cannot feel by any means certain that he is not ten or twenty ft in error; and this may occur without any *perceptible* change in the atmosphere Whenever practicable, therefore, there should be a person at each station, to observe at both points at the same time. Single observations at points many miles apart and made on different days, and in different states of the atmosphere, are of little value In such cases the mean of many observations, extending over several days, weeks, or months, and made when the air is apparently undisturbed, will give tolerable approximations to the truth. In the tropics the range of the atmospheric pres is much less than in other regions, seldom exceeding ½ inch at any one spot, also more regular in time, and, therefore, less productive of error. Still, the barometer, especially either the aneroid, or Bourdon's metallic, may be rendered highly useful to the civil engineer, in cases where great accuracy is not demanded. By hurrying from point to point, and especially by repeating, he can form a judgment as to which of two summits is the lowest Or a careful observer, keeping some miles ahead of a surveying party, may materially lessen their labors, especially in a rough country, by selecting the general route for them in advance. The accounts of the agreement within a few inches, in the measurements of high mountains, by diff observers, at diff periods; and those of ascertaining accurately the grades of a railroad, by means of an aneroid, while riding in a car, will be believed by those only who are ignorant of the subject. Such results can happen only by chance.

When possible, the observations at different places should be taken at the same time of day, as some check upon the effects of the daily atmospheric tides; and in very important cases, a memorandum should be made of the year, month, day, and hour, as well as of the state of the weather, direction of the wind, latitude of the place, &c, to be referred to an expert, if necessary.

The effects of latitude are not included in any of our formulas. When reqd they may be found in the table page 314. Several other corrections must be made when great accuracy is aimed at; but they require extensive tables.

In rapid railroad exploring, however, such refinements may be neglected, inasmuch as no approach to such accuracy is to be expected; but on the contrary, errors of from 1 to 10 or more feet in 100 of height, will frequently occur.

As a very rough average we may assume that the barometer falls $\frac{1}{10}$ inch for every 90 feet that we ascend above the level of the sea, up to 1000 ft. But in fact its rate of fall decreases continually as we rise; so that at one mile high it falls $\frac{1}{10}$ inch for about 106 ft rise. Table 2 shows the true rate.

To ascertain the diff of height between two points.

RULE 1. Take readings of the barom and therm (Fah) **in the shade** at both stations. Add together the two readings of the barom, and div their sum by 2, for their mean; which call b. Do the same with the two readings of the thermom, and call the mean t. Subtract the least reading of the barom from the greatest; and call the diff d. Then mult together this diff d; the number from the next Table No. 1, opposite t; and the constant number 30. Div the prod by b. Or

$$\text{Height in feet} = \frac{\text{Diff } (d) \text{ of barom} \times \text{Tabular number opposite mean } (t) \text{ of thermom} \times \text{Constant } 30.}{\text{mean } (b) \text{ of barom}}$$

EXAMPLE. Reading of the barom at lower station, 26.64 ins; and at the upper sta 20.82 ins. Thermom at lowest sta, 70°; at upper sta, 40°. What is the diff in height of the two stations? Here,

Barom, 26.64		Therm, 70°
" 20.82	Also,	" 40°
2)47.46		2)110
23.73 mean of bar, or b.		55° mean of therm, or t.

The tabular number opposite 55°, is 917.2.

Again, 26.64 — 20.82 = 5.82, diff of bar; or d. Hence,

$$\text{Height in feet} = \frac{\overset{d,}{5.82} \times \overset{\text{Tab No.}}{917.2} \times \overset{\text{Con.}}{30}}{23.73 \text{ (or } b)} = \frac{160143.12}{23.73} = 6748.5 \text{ ft; answer.}$$

Then correct for latitude, if more accuracy is reqd, by rule on next page.

The screw at the back of an aneroid is for adjusting the index by a standard barom. After this has been done it must by no means be meddled with. In some instruments specially made to order with that intention, this screw may be used also for turning the index back, after having risen to an elevation so great that the index has reached the extreme limit of the graduated arc. After thus turning it back, the indications of the index at greater heights must be added to that attained when it was turned back.

29	862.3	59	925.6	89	988.9	119	1052.2

RULE 2. **Belville's short approx rule** is the one best adapted to rapid field use, namely, add together the two readings of the barom only. Also find the diff between said two readings; then, **as the sum of the two readings is to their diff, so is 55000 feet to the reqd altitude.**

Correction for latitude is usually omitted where great accuracy is not required. To apply it, first find the altitude by the rule, as before. Then divide it by the number in the following table opposite the latitude of the place (If the two places are in different latitudes, use their mean.) *Add* the quotient to the altitude if the latitude is *less* than 45°. *Subtract* it if the latitude is *more* than 45°. No correction required for latitude 45°.

Table of corrections for latitude.

Lat.		Lat.		Lat		Lat.		Lat		Lat

Levelling by Barometer; or by the boiling point.

RULE 3. The following table, No. 2, enables us to measure heights either by means of boiling water, or by the barom The third column shows the approximate altitude above sea-level corresponding to diff heights, or readings of the barom; and to the diff degrees of Fahrenheit's thermom, at which water boils in the open air Thus when the barom, under undisturbed conditions of the atmosphere, stands at 24.08 inches, or when pure rain or distilled water boils at the temp of 201° Fah; the place is about 5764 ft above the level of the sea, as shown by the table. It is therefore very easy to find the *diff* of altitude of two places Thus: take out from table No 2, the altitudes opposite to the two boiling temperatures; or to the two barom readings Subtract the one opposite the lower reading, from that opposite the upper reading The rem will be the reqd height, as a rough approximation To correct this, add together the two therm readings; and div the sum by 2, for their mean. From table for temperature, p 316, take out the number opposite this mean. Mult the approximate height just found, by this tabular number. Then correct for lat if reqd.

EX. The same as preceding; namely, barom at lower sta, 26.64; and at upper sta, 20.82. Thermom at lower sta, 70° Fah; and at the upper one, 40°. What is the diff of height of the two stations?

	Alt.
Here the tabular altitudes are, for 20.82........ ...	9579
and for 26.64......	3115
	6464 ft, approx height.

To correct this, we have $\frac{70° + 40°}{2} = \frac{110°}{2} = 55°$ mean; and in table p 316, opp to 55°, we find 1.048. Therefore $6464 \times 1.048 = 6774$ ft, the reqd height.

This is about 26 ft more than by Rule 1; or nearly .4 of a ft in each 100 ft.

At 70° Fah, pure water will boil at 1° less of temp, for an average of about 550 ft of elevation above sea-level, up to a height of ½ a mile. At the height of 1 mile, 1° of boiling temp will correspond to about 560 ft of elevation. In table p 315 the mean of the temps at the two stations is assumed to be 32° Fah; at which no correction for temp is necessary in using the table; hence the tabular number opposite 32°, in table p 316, is 1.

This diff produced in the temp of the *boiling point*, by change of elevation, must not be confounded with that of the *atmosphere*, due to the same cause. The air becomes cooler as we ascend above sea-level, at the rate (very roughly) of about 1° Fah for every 200 ft near sea-level, to 350 ft at the height of 1 mile.

The following table, No. 2, (so far as it relates to the barom) was deduced by the writer from the standard work on the barom by Lieut.-Col. R. S. Williamson, U. S. army.*

* Published by permission of Government in 1868 by Van Nostrand, N. Y

SOUND.

The velocity of sound in quiet open air, has been experimentally determined to be very approximately 1090 feet per second, when the temperature is at freezing point, or 32° Fahrenheit. For every degree Fahrenheit of increase of temperature, the velocity increases by from ½ foot to 1¼ feet per second, according to different authorities. Taking the increase at 1 foot per second for each degree (which agrees closely with theoretical calculations), we have

at	−	30°	Fahr	1030	feet	per sec	= 0.1951	mile	per sec	= 1	mile	in	5.13	seconds.

If the air is calm, fog or rain does not appreciably affect the result; but winds do. Very loud sounds appear to travel somewhat faster than low ones. The watchword of sentinels has been heard across still water, on a calm night, 10½ miles; and a cannon 20 miles. Separate sounds, at intervals of $\frac{1}{16}$ of a second, cannot be distinguished, but appear to be connected. The distances at which a speaker can be understood, in front, on one side, and behind him are about as 4, 3, and 1.

Dr. Charles M Cresson informs the writer that, by repeated trials, he found that in a Philadelphia gas main 20 inches diameter and 16000 feet long, laid and covered in the earth, but empty of gas, and having one horizontal bend of 90°, and of 40 feet radius the sound of a pistol-shot travelled 16000 feet in precisely 16 seconds, or 1000 feet per second. The arrival of the sound was barely audible; but was rendered very apparent to the eye by its blowing off a diaphragm of tissue-paper placed over the end of the main.

Two boats anchored some distance apart may serve as a base line for triangulating objects along the coast; the distance between them being first found by firing guns on board one of them.

In water the velocity is about 4708 feet per second, or about 4 times that in air. **In woods,** it is from 10 to 16 times; and **in metals,** from 4 to 16 times greater than in air, according to some authorities.

Approximate expansion of solids by heat; and their melting points by Fahrenheit's thermometer.‡

Let a_c or a_f = the **linear expansion coefficient** of a material = that fraction of its original length which a prismatic bar, of that material, gains or loses, for each degree, Cent. or Fahr. respectively, of change in its temperature. Then: $a_c = \frac{9}{5} a_f$; $a_f = \frac{5}{9} a_c$.

The coefficient is practically constant at ordinary temperatures.

The force. exerted longitudinally by such a bar, in expanding or contracting, is $P = a\,t\,E\,F$, where a = coefficient, as above; t = change in temperature, in degrees; E = elastic modulus (see p 456); F = area of cross section. **The work,** done by this force, in expanding or contracting the bar, of original length, L, through the length, l, is $W = P\,l = P\,L\,a\,t = a^2\,t^2\,E\,F\,L$.

The superficial expansion coefficient (ratio of change of area of a surface to its original area) = about $2\,a$; **voluminar coefficient** = about $3\,a$; assuming that the linear coefficient is the same in all directions.

Heat of a common wood fire variously estimated at from 800° to 1140° Fahr.; charcoal fire, about 2200° F.; coal fire, about 2400° F.

* By adding $\frac{1}{10}$ part to the lengths in the two cols under 180°, we get the lengths corresponding to a number of degrees $\frac{1}{11}$ less than 180°; or to 163°.63 deg which may be taken as about the *extremes* of temp in the colder portions of the United States. In the Middle States the extremes rarely reach 135°, or ¼ part less than 180°.

No dependence whatever is to be placed on results obtained by Wedgewood's pyrometer.

† The table shows that the contraction and **expansion of stone** will cause open joints in winter; and crushing of the mortar in summer, at the ends of long coping-stones.

‡ **The melting points are quite uncertain.** We give the mean of the best authorities. Assuming that with a change of temp of about 163°, wrought iron will alter its length 1 part in 916; this in a mile amounts to 5 764 ft, or about 5 ft 9¼ ins; and in 100 ft to .109 of a foot; or 1⅜ ins; so that a diff of 5 ft, or more, can readily result from measuring a mile in winter and in summer with the same chain; and a 25 ft rail will change its length full ⅜ of an inch.

THERMOMETERS.

Let C, R, F = the given reading, in degrees Celsius (Centigrade), Réaumur, ahrenheit, respectively. Then (See tables 1, 2, 3, below):

$$C = \frac{5}{4} R = \frac{5}{9} (F - 32);$$

$$R = \frac{4}{5} C = \frac{4}{9} (F - 32);$$

$$F = \frac{9}{5} C + 32 = \frac{9}{4} R + 32.$$

hus, let $F = -40$. Then $C = \frac{5}{9}(-40 - 32) = -40$. For **expan-ion coefficients**, see p 317.

Below about —37° C (= —30° R = —35° F), the mercurial thermometer nd barometer become irregular. Mercury begins to freeze at about —40° C —32° R = —40° F. Below this temperature alcohol is used.

TABLE 1. Fahrenheit compared with Centigrade and Réaumur. In *this* table the Cent and Réau readings are given to the nearest decimal.

AIR.—ATMOSPHERE.

The atmosphere is known to extend to at least 45 miles above the earth. It is a mixture of about 79 measures of nitrogen gas and 21 of oxygen gas; or about 77 nitrogen, 23 oxygen, by weight. It generally contains, however, a trace of water, and of carbonic acid and carburetted hydrogen gases, and still less ammonia.

Density of air. Under "normal" or "standard" conditions (sea level, lat 45°, barometer 760 mm = 29.922 ins, temperature 0° C = 32° F) **dry air weighs** 1.292673 kilograms per cubic meter * = 2.17888 lbs avoir per cubic yard. For other lats and elevations—

$$\text{Density, in kg per cu m,} = 1.292673 \times \frac{R}{R + 2h} \times (1 - 0.002837 \cos 2 \text{ lat})^*$$

where R = earth's mean radius = 6,366,198 meters; h = elevation above sea level, in meters. For other temperatures, see below.

Under normal conditions, but with 0.04 parts carbonic acid (CO_2) in 100 parts of air, density = 1.293052 kg per cu m.† = 2.17952 lbs avoir per cu yd.‡

The atmospheric pressure, at any given place, may vary 2 inches or more from day to day. **The average pressure,** at sea level § varies from about 745 to 770 millimeters of mercury according to the latitude and locality. 760 millimeters* is generally accepted as the mean atmospheric pressure, and called **an atmosphere.** The "**metric atmosphere,**" taken arbitrarily at 1 kilogram per square centimeter, is in general use in Continental Europe. The pressure diminishes as the altitude increases.† Therefore, a pump in a high region will not lift water to as great a height as in a low one. The pressure of air, like that of water, is, at any given point, equal in all directions.

It is often stated that the **temperature of the atmosphere** lowers at the rate of 1° Fah for each 300 feet of ascent **above the earth's surface;** but this is liable to many exceptions, and varies much with local causes. Actual observation in balloons seems to show that, up to the first 1000 feet, 1° in about 200 feet is nearer the truth; at 2000 feet, 1° in 250 feet; at 4000 feet, 1° in 300 feet; and, at a mile, 1° in 350 feet.

In breathing, a grown person at rest requires from 0.25 to 0.35 of a cubic foot of air per minute; which, when breathed, vitiates from 3.5 to 5 cubic feet. When walking, or hard at work, he breathes and vitiates two or three times as much. About 5 cubic feet of fresh air per person per minute are required for the perfect ventilation of rooms in winter; 8 in summer. Hospitals 40 to 80.

Beneath the general level of the surface of the earth, in temperate regions, a tolerably uniform **temperature** of about 50° to 60° Fah exists at the depth of about 50 to 60 feet; and increases about 1° for each additional 50 to 60 feet; all subject, however, to considerable deviations owing to many local causes. In the Rose Bridge Colliery, England, at the depth of 2424 feet, the temperature of the coal is 93.5° Fah; and at the bottom of a boring 4169 feet deep, near Berlin, the temperature is 119°.

The air is a very slow conductor of heat; hence hollow walls serve to retain the heat in dwellings; besides keeping them dry. **It rushes into a vacuum** near sea level with a velocity of about 1157 feet per second; or 13.3 miles per minute; or about as fast as sound ordinarily travels through quiet air. See Sound.

Like all other elastic fluids, air expands equally with equal increases of temperature. Every increase of 5° Fah, expands the bulk of any of them slightly more than 1 per cent of that which it has at 0° Fah; or 500° about doubles its bulk at zero. The bulk of any of them diminishes inversely in proportion to the total **pressure** to which it is subjected.

This holds good with air at least up to pressures of about 750 lbs per square inch, or 50 times its natural pressure; the air in this case occupying one-fiftieth of its natural bulk. In like manner the bulk will increase as the total pressure is diminished. Substances which follow these laws, are said to be **perfectly**

---

* H. V. Regnault, Mémoires de l'Académie Royale des Sciences de l'Institut de France, Tome XXI, 1847. Translation in abstract, Journal of Franklin Institute, Phila., June, 1848.

† Travaux et Mémoires du Bureau International des Poids et Mesures, Tome 1, page A 54. Smithsonian Meteorological Tables, 1893, published in Smithsonian Miscellaneous Collections, Vol. XXXV, 1897.

‡ See Conversion Tables.

§ See Leveling by the Barometer.

elastic. Under a pressure of about 5½ tons per square inch, air would become as dense as water. Since the air at the surface of the earth is pressed 14¾ lbs per square inch by the atmosphere above it, and since this is equal to the weight of a column of water 1 inch square and 34 feet high, it follows that at the depths of 34, 68, 102 feet, &c, **below water,** air will be compressed into ½, ⅓, ¼, &c, of its bulk at the surface.

In a diving-bell, men, after some experience, can readily work for several hours at a depth of 51 feet, or under a pressure of 2½ atmospheres; or 37½ lbs per square inch. But at 90 feet deep, or under 3.64 atmospheres, or nearly 55 lbs per square inch, they can work for but about an hour, without serious suffering from paralysis, or even danger of death. Still, at the St. Louis bridge, work was done at a depth of 110½ feet; pressure 63.7 lbs per square inch.

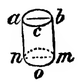
The dew point is that temp (varying) at which the air deposits its vapor.

The greatest heat of the air in the sun probably never exceeds 145° Fah, nor the greatest cold —74° at night. About 130° above, and 40° below zero, are the extremes in the U. S east of the Mississippi; and 65° below in the N. W.; all at common ground level. It is stated, however, that —81° has been observed in N. E. Siberia; and +101° Fah in the shade in Paris; and +153° in the sun at Greenwich Observatory, both in July, 1881. It has frequently exceeded +100° Fah in the shade in Philadelphia during recent years.

WIND.

The relation between the velocity of wind, and its pressure against an obstacle placed either at right angles to its course, or inclined to it, has not been well determined; and still less so its pressure against curved surfaces The pressure against a large surface is probably proportionally greater than against a small one. It is generally supposed to vary nearly as the squares of the velocities; and when the obstacle is at right angles to its direction, the pressure in lbs per square foot of exposed surface is considered to be equal to the square of the velocity in miles per hour, divided by 200. On this basis, which is probably quite defective, the following table, as given by Smeaton, is prepared. See also pp 710, 711, 713, 714, 758, 759, 764.

Vel. in Miles per Hour	Vel in Ft. per Sec.	Pres. in Lbs. per Sq Ft.	Remarks
1	1 467	005	Hardly perceptible.
2	2 933	020	Pleasant.
3	4 400	045	
4	5 867	080	
5	7 33	125	
10	14 67	.5	
12½	18.33	781	Fresh breeze.
15	22.	1 125	
20	29 33	2	
25	36 67	3 125	Brisk wind
30	44	4 5	Strong wind.
40	58 67	8	High wind.
50	73 33	12 5	Storm
60	88	18.	Violent storm.
80	117 3	32	Hurricane
100	146 7	50.	Violent hurricane, uprooting large trees.



The pres against a semicylindrical surface *a c b n o m* is about half that against the flat surf *a b n m*.

Tredgold recommends to allow 40 lbs per sq ft of roof for the pres of wind against it; but as roofs are constructed with a slope, and consequently do not receive the full force of the wind, this is plainly too much * Moreover, only one-half of a roof is usually exposed, even thus partially, to the wind. Probably the force in such cases varies approximately as the sines of the angles of slopes According to observations in Liverpool, in 1860, a wind of 38 miles per hour, produced a pres of 14 lbs per sq ft against an object perp to it: and one of 70 miles per hour, (the severest gale on record at that city,) 42 lbs per sq foot. These would make the pres per sq ft, more nearly equal to the square of the vel in miles per hour, div by 100, or nearly twice as great as given in Smeaton's table. We should ourselves give the preference to the Liverpool observations. A very violent gale in Scotland, registered by an excellent anemometer, or wind-gauge, 45 lbs per sq ft. It is stated that as high as 55 lbs has been observed at Glasgow. High winds often *lift* roofs.

The gauge at Girard College, Philada, broke under a strain of 42 lbs per sq ft; a tornado passing at the moment, within ¼ mile

By inversion of Smeaton's rule, if the force in lbs per sq ft, be mult by 200, the sq rt of the prod will give the vel in miles per hour

* The writer thinks 8 lbs per sq foot of *ordinary double-sloping roofs*, or 16 lbs for *shed-roofs*, sufficient allowance for pres of wind.

RAIN AND SNOW.

The annual precipitation* at any given place varies greatly from year to year, the ratio between maximum and minimum being frequently greater than 2 : 1. **Beware of averages.** In estimating *floods*, take the *maximum* falls, and in estimating *water supply*, the *minimum*, not only per annum, but for short periods. In estimating water supply, make deductions for evaporation and leakage.

Maxima and minima deduced from observations covering only 4 or 5 years are apt to be misleading. Data covering even 10 or more years may just miss including a very severe flood or drought. Records of from 15 to 20 years may usually be accepted as sufficient.

Table 1. Average Precipitation * † in the United States, in ins. (From Bulletin C of U. S. Department of Agriculture, compiled to end of 1891.)

At Philadelphia, in 1869, during which occurred the greatest drought known there for at least 50 years, 43.21 inches fell; August 13, 1873, 7.3 inches in 1 day; August, 1867, 15.8 inches in 1 month; July, 1842, 6 inches in 2 hours; 9 inches per month not more than 7 or 8 times in 25 years. From 1825 to 1893, greatest in one year, 61 inches, in 1867; least, 30 inches, in 1825 and 1880. At Norristown, Pennsylvania, in 1865, the writer saw evidence that at least 9 inches fell within 5 hours. At Genoa, Italy, on one occasion, 32 inches fell in 24 hours; at Geneva, Switzerland, 6 inches in 3 hours; at Marseilles, France, 13 inches in 14 hours; in Chicago, Sept., 1878, .97 inch in 7 minutes.

Near London, England, the mean total fall for many years is 23 inches. On one occasion, 6 inches fell in 1½ hours! In the mountain districts of the English lakes, the fall is enormous; reaching in some years to 180 or 240 inches; or from 15 to 20 feet! while, in the adjacent neighborhood, it is but 40 to 60 inches. At Liverpool, the average is 34 inches; at Edinburgh, 30; Glasgow, 22; Ireland, 36; Madras, 47; Calcutta, 60; maximum for 16 years, 82; Delhi, 21; Gibraltar, 30; Adelaide, Australia, 23; West Indies, 36 to 96; Rome, 39. On the Khassya hills north of Calcutta, 500 inches, or 41 feet 8 inches, have fallen in the 6 rainy months! In other mountainous districts of India, annual falls of 10 to 20 feet are common.

A moderate steady rain, continuing 24 hours, will yield a depth of about an inch.

As a general rule, more rain falls in warm than in cold countries; and more in elevated regions than in low ones. Local peculiar-

---

* Precipitation includes snow, hail, and sleet, melted.

† Unmelted snow is here estimated at 10 inches snow = 1 inch rain. But see "Rainfall equivalent of snow," p 324.

ities, however, sometimes reverse this; and also cause great differences in the amounts in places quite near each other; as in the English lake districts just alluded to. It is sometimes difficult to account for these variations. In some lagoons in New Granada, South America, the writer has known three or four heavy rains to occur weekly for some months, during which not a drop fell on hills about 1000 feet high, within ten miles' distance, and within full sight. At another locality, almost a dead-level plain, fully three-quarters of the rains that fell for two years, at a spot two miles from his residence, occurred in the morning; while those which fell about three miles from it, in an opposite direction, were in the afternoon.

The relation between precipitation and stream-flow is greatly affected by the existence of forests or crops, by the slope and character of ground on the water-shed, especially as to rate of absorption, by the season of the year, the frost in the ground, etc. The stream-flow may ordinarily be taken as varying between 0 2 and 0 8 of the rainfall. Streams in limestone regions frequently lose a very large proportion of their flow through subterranean caverns.

Assuming a fall of 2 feet in 1 year (= 76,379 cubic feet per square mile per day), that half the rainfall is available for water supply, and that a per capita consumption of 4 cubic feet (= 30 gallons) per day is sufficient, one square mile will supply 19,095 persons; or a square of 38.25 feet on a side will supply one person.

An inch of rain amounts to 3630 cubic feet; or 27155 U. S. gallons; or 101.3 tons per acre; or to 2323200 cubic feet; or 17378743 U. S. gallons; or 64821 tons per square mile at 62½ lbs per cubic foot.

The most destructive rains are usually those which fall upon snow, under which the ground is frozen, so as not to absorb water.

Table 2. Maximum intensity of rainfall for periods of 5, 10, and 60 minutes at Weather Bureau stations equipped with self-registering gauges, compiled from all available records to the end of 1896.

(From Bulletin D of U. S. Department of Agriculture.)

The weight of freshly fallen snow, as measured by the author, varies from about 5 to 12 lbs per cubic foot; apparently depending chiefly upon the degree of humidity of the air through which it had passed. On one occasion, when mingled snow and hail had fallen to the depth of 6 inches, he found its weight to be 31 lbs per cubic foot. It was very dry and incoherent. A cubic foot of heavy snow may, by a gentle sprinkling of water, be converted into about half a cubic foot of slush, weighing 20 lbs.; which will not **slide or run off** from a shingled roof sloping 30°, if the weather is cold. A cubic block of snow saturated with water until it weighed 45 lbs per cubic foot, just slid on a rough board inclined at 45°; on a smoothly planed one at 30°; and on slate at 18°; all approximate. A prism of snow, saturated to 52 lbs per cubic foot, one inch square, and 4 inches high, **bore a weight** of 7 lbs; which at first compressed it about one-quarter part of its length. European engineers consider 6 lbs per square foot of roof to be sufficient **allowance for the weight of snow**

and 8 lbs for the pressure of wind; total, 14 lbs. The writer thinks that in the U. S. the allowance for snow should not be taken at *less* than 12 lbs; or the total for snow and wind, at 20 lbs. There is no danger that snow on a roof will become saturated to the extent just alluded to; because a rain that would supply the necessary quantity of water would also by its violence wash away the snow; but we entertain no doubt whatever that the united pressures from snow and wind, in our Northern States, do actually at times reach, and even surpass, 20 lbs per square foot of roof. **The limit of perpetual snow** at the equator is at the height of about 16000 feet, or say 3 miles above sea-level; in lat 45° north or south, it is about half that height; while near the poles it is about at sea-level.

Rain Gauges. Plain cylindrical vessels are ill adapted to service as rain gauges; because moderate rains, even though sufficient to yield a large run-off from a moderate area, are not of sufficient depth to be satisfactorily measured unless the depth be exaggerated. The inaccuracy of measurement, always considerable, is too great relatively to the depth.

In its simplest and most usual form, the gauge (see Fig.) consists essentially of a funnel, A, which receives the rain and leads it into a measuring tube, B, of smaller cross-section. The funnel should have a vertical and fairly sharp edge, and, in order to minimize the loss through evaporation, it should fit closely over the tube, and its lower end should be of small diameter.

The depth of water in the tube is ascertained by inserting, to the bottom of the tube, a measuring stick of some unpolished wood which will readily show to what depth it has been wet. The stick may be permanently graduated, or it may be compared with an ordinary scale at each observation. The tube is usually of such diameter that the area of its cross-section, minus that of the stick, is one-tenth of the area of the funnel mouth. The depth of rainfall is then one-tenth of the depth as measured by the stick.

DIMENSIONS OF STANDARD U. S. WEATHER BUREAU RAIN GAUGE.				Ins.
A.	Receiver or funnel.		Diameter	8
B.	Measuring tube.	Height 20 ins.	"	2.53
C C.	Overflow attachment and snow gauge.		"	8

Such gauges, with the tubes carefully made from seamless drawn brass tubing, cost about $5.00 each; but an intelligent and careful tinsmith, given the dimensions accurately, can construct, of galvanized iron, for about $1.00 a gauge that will answer every purpose of the engineer.

The exposure has a very marked effect upon the results obtained. The funnel should be elevated about 3 ft, in order to prevent rain from splashing back into it from the ground or roof. If on a roof, the latter should be flat, and preferably 50 ft wide or wider, and the gauge should be placed as far as possible from the edges; else the air currents, produced by the wind striking the side of the building, will carry some of the rain over the gauge. No objects much higher than the gauge should be near it, as they produce variable air currents which may seriously affect its indications.

An overflow tank, C, should be provided, for cases of overfilling the tube.

Water, freezing in the gauge, may burst it, or force the bottom off, or at least so deform the gauge as to destroy its accuracy.

To measure snow, the funnel is removed, and the snow is collected in the overflow attachment or other cylindrical vessel deep enough to prevent the snow from being blown out, and the cross-sectional area of which is accurately known. The snow is then melted, either by allowing it to stand in a warm place, or, with less loss through evaporation, by adding an accurately known quantity of luke-warm water. In the latter case, the volume of the added water must of course be deducted from the measurement.

Rainfall equivalent of snow. Ten inches of snow are usually taken as equivalent to 1 in of rain; but, according to various authorities, the equivalent may vary between 2½ and 34; *i. e.*, between 25 and 1.84 lbs. per cubic foot.

Self-recording gauges, of which several forms are on the market, are quite expensive, and, even when purchased from regular makers, seldom perfectly reliable. Gauges using a small tipping bucket register inaccurately in heavy rains; those using a float are limited as to the total depth which they can register; while those which weigh the rain, if exposed, are affected by wind.

ities, however, sometimes reverse this; and also cause great differences in the amounts in places quite near each other; as in the English lake districts just alluded to. It is sometimes difficult to account for these variations. In some lagoons in New Granada, South America, the writer has known three or four heavy rains to occur weekly for some months, during which not a drop fell on hills about 1000 feet high, within ten miles' distance, and within full sight. At another locality, almost a dead-level plain, fully three-quarters of the rains that fell for two years, at a spot two miles from his residence, occurred in the morning; while those which fell about three miles from it, in an opposite direction, were in the afternoon.

The relation between precipitation and stream-flow is greatly affected by the existence of forests or crops, by the slope and character of ground on the water-shed, especially as to rate of absorption, by the season of the year, the frost in the ground, etc. The stream-flow may ordinarily be taken as varying between 0.2 and 0.8 of the rainfall. Streams in limestone regions frequently lose a very large proportion of their flow through subterranean caverns.

Assuming a fall of 2 feet in 1 year (= 76,379 cubic feet per square mile per day), that half the rainfall is available for water supply, and that a per capita consumption of 4 cubic feet (= 30 gallons) per day is sufficient, one square mile will supply 19,095 persons; or a square of 38.25 feet on a side will supply one person.

An inch of rain amounts to 3630 cubic feet; or 27155 U. S. gallons; or 101.3 tons per acre; or to 2323200 cubic feet; or 17378743 U. S. gallons; or 64821 tons per square mile at 62½ lbs per cubic foot.

The most destructive rains are usually those which fall upon snow, under which the ground is frozen, so as not to absorb water.

The weight of freshly fallen snow, as measured by the author, varies from about 5 to 12 lbs per cubic foot; apparently depending chiefly upon the degree of humidity of the air through which it had passed. On one occasion, when mingled snow and hail had fallen to the depth of 6 inches, he found its weight to be 31 lbs per cubic foot. It was very dry and incoherent. A cubic foot of heavy snow may, by a gentle sprinkling of water, be converted into about half a cubic foot of slush, weighing 20 lbs.; which will not **slide or run off** from a shingled roof sloping 30°, if the weather is cold. A cubic block of snow saturated with water until it weighed 45 lbs per cubic foot, just slid on a rough board inclined at 45°; on a smoothly planed one at 30°; and on slate at 18°; all approximate. A prism of snow, saturated to 52 lbs per cubic foot, one inch square, and 4 inches high, **bore a weight** of 7 lbs; which at first compressed it about one-quarter part of its length. European engineers consider 6 lbs per square foot of roof to be sufficient **allowance for the weight of snow**

WATER.

PURE water, as boiled and distilled, **is composed of** the two gases, hydrogen and oxygen; in the proportions of 2 measures hydrogen to 1 of oxygen; or 1 weight of hydrogen to 8 of oxygen. Ordinarily, however, it contains several foreign ingredients, as carbonic and other acids; and soluble mineral, or organic substances. When it contains much lime, it is said to be *hard*; and will not make a good lather with soap. **The air** in its ordinary state **contains** about 4 grains of water per cubic foot.

The average **pressure of the air at sea level, will balance a column of water** 34 feet high; or about 30 inches of mercury.

Weight of unit volume, as affected by temperature. barometer at 30 ins:

Temp, Fahr,	32°	39.2°	40°	50°	60°	70°	80°	90°	212°
Temp, Cent,	0°	4°	4.4°	10°	15.6°	21.1°	26 7°	32 2°	100°
lbs/cu ft,	62.417	62.428	62.423	62 409	62.367	62.302	62 218	62.119	59.700
grams/cu cm,	0.9998	1.0000	0.9999	0.9997	0 9990	0.9980	0.9966	0 9950	0.9563

Maximum density at 4° C = 39.2° F; 1 gram/cu cm = 62.428 lbs/cu ft. From this temp, it expands, either by heat or by cold.

At 62° F (16.7° C), barom, 30 ins; weight of water = about **815 × weight of air.**

Sea water. Weight of unit volume; 64 to 64 27 lbs per cu ft = 1.026 to 1.029 grams per cu cm. See also p 328.

Ice. Weight of unit volume; 57 2 lbs/cu ft = 0.916 gram/cu cm. (L. Dufour)

Hence, as ice, it has expanded one-twelfth of its original bulk as water; and the **sudden expansive force** exerted at the moment of freezing, is sufficiently great to split iron water-pipes; being probably not less than 30,000 lbs per square inch. Instances have occurred of its splitting cast tubular posts of iron bridges, and of ordinary buildings, when full of rain water from exposure. It also loosens and throws down masses of rock, through the joints of which rain or spring water has found its way. Retaining-walls also are sometimes overthrown, or at least bulged, by the freezing of water which has settled between their backs and the earth filling which they sustain; and walls which are not founded at a sufficient depth, are often lifted upward by the same process.

It is said that **in a glass tube ¼ inch in diameter,** water will not freeze until the temperature is reduced to 23°; and in tubes of less than $\frac{1}{20}$ inch, to 3° or 4°. Neither will it freeze until considerably colder than 32° in rapid running streams. **Anchor ice,** sometimes found at depths as great as 25 feet, consists of an aggregation of small crystals or needles of ice frozen at the surface of rapid open water; and probably carried below by the force of the stream. It does not form under frozen water.

Since ice floats in water: and a floating body displaces a weight of the liquid equal to its own weight, it follows that a cubic foot of floating ice weighing 57 2 lbs, must displace 57.2 lbs of water. But 57.2 lbs of water, one foot square, is 11 inches deep: therefore, floating ice of a cubical or parallelopipedal shape, will have $\frac{11}{12}$ of its volume under water; and only $\frac{1}{12}$ above; and a square foot of ice of any thickness, will require a weight equal to $\frac{1}{11}$ of its own weight to sink it to the surface of the water. In practice, however, this must be regarded merely as a close approximation, since the weight of ice is somewhat affected by enclosed air-bubbles.

Pure water is usually assumed to **boil** at 212° Fah in the open air, at the level of the sea; the barometer being at 30 inches; and at about 1° less for every 520 feet above sea level, for heights within 1 mile. In fact, its boiling point varies like its freezing point, with its purity, the density of the air, the material of the vessel, &c. In a metallic vessel, it may boil at 210°; and in a glass one, at from 212° to 220°; and it is stated that if all air be previously extracted, it requires 275°.

It evaporates at all temperatures; **dissolves** more substances than any other agent: and has a greater capacity for heat than any other known substance.

Compression, per atmosphere (14.7 lbs/sq in) about 1 in 21,740. The volume is restored when the pres is removed.

Effect on metals. The lime contained in many waters, forms deposits in metallic water-pipes, and in channels of earthenware, or of masonry, especially if the current be slow. Some other substances do the same; obstructing the flow of the water to such an extent, that it is always expedient to use pipes of diameters larger than would otherwise be necessary. The lime also forms very hard **incrustations at the bottoms of boilers**; very much impairing their efficiency; and rendering them more liable to burst. Such water is unfit for locomotives. We have seen it stated that the Southwestern R R Co, England, prevent this lime deposit, along their limestone sections, by dissolving 1 ounce of sal-ammoniac to 90 gallons of water. The salt of sea water forms similar deposits in boilers; as also does mud, and other impurities.

Water, either when very pure, as rain water; or when it contains carbonic acid, (as most water does,) **produces carbonate of lead in lead pipes**; and as this is an active poison, such pipes should not be used for such waters. Tinned lead pipes may be substituted for them. If, however, sulphate of lime also be present, as is very frequently the case, this effect is not always produced; and several other substances usually found in spring and river water, also diminish it to a greater or less degree. **Fresh water corrodes wrought iron more rapidly than cast**; but the reverse appears to be the case with **sea water**; although it also affects wrought iron very quickly; so that thick flakes may be detached from it with ease. The corrosion of iron or steel by sea water increases with the carbon. Cast-iron cannons from a vessel which had been sunk in the fresh water of the Delaware River for more than 40 years, were perfectly free from rust. Gen. Pasley, who had examined the metals found in the ships Royal George, and Edgar, the first of which had remained sunk in the sea for 62 years, and the last for 133 years, "stated that the cast iron had generally become quite soft; and in some cases resembled plumbago. Some of the shot when exposed to the air became hot; and burst into many pieces. The wrought iron was not so much injured, *except when in contact with copper, or brass gun-metal.* Neither of these last was much affected, except when in contact with iron. Some of the wrought iron was reworked by a blacksmith, and pronounced superior to modern iron." "Mr. Cottam stated that some of the guns had been carefully removed in their soft state, to the Tower of London; and in time (within 4 years) *resumed their original hardness.* Brass cannons from the Mary Rose, which had been sunk in the sea for 292 years, were considerably honeycombed in spots only; (perhaps where iron had been in contact with them) The old cannons, of wrought-iron bars hooped together, were corroded about ¼ inch deep; but had probably been protected by mud. The cast-iron shot became redhot on exposure to the air; and fell to pieces like dry clay!"

"Unprotected parts of cast-iron sluice-valves on the sea gates of the Caledonian canal were converted into a soft plumbaginous substance, to a depth of ¾ of an inch, within 4 years; but where they had been coated with common Swedish tar, they were entirely uninjured This softening effect on cast iron appears to be as rapid even when the water is but slightly brackish; and that only at intervals. It also takes place on cast iron imbedded in salt earth. Some water pipes thus laid near the Liverpool docks, at the expiration of 20 years were soft enough to be cut by a knife; while the same kind, on higher ground beyond the influence of the sea water, were as good as new at the end of 50 years."

Observation has, however, shown that **the rapidity of this action depends much on the quality of the iron**; that which is dark-colored and contains much carbon mechanically combined with it, corrodes most rapidly: while hard white, or light-gray castings remain secure for a long time. Some cast-iron sea-piles of this character, showed no deterioration in 40 years.

Contact with brass or copper is said to induce a galvanic action which greatly hastens decay in either fresh or salt water. Some muskets were recovered from a wreck which had been submerged in sea water for 70 years near New York. The brass parts were in perfect condition; but the iron parts had entirely disappeared. **Galvanizing** (coating with zinc) acts as a preservative to the iron, but at the expense of the zinc, which soon disappears. The iron then corrodes. If iron be well heated, and then coated with **hot coal-tar**, it will resist the action of either salt or fresh water for many years. It is very important that the tar be perfectly *purified.* Such a coating, or one of paint, will not prevent **barnacles and other shells** from attaching themselves to the iron. Asphaltum, if pure, answers as well as coal-tar.

Copper and bronze are very little affected by sea water.

No galvanic action has been detected where brass ferules are inserted into the water-pipes in Philadelphia.

The most prejudicial exposure for iron, as well as for wood, is that to alternate wet and dry. At some dangerous spots in Long Island Sound, it has been the practice to drive round bars of rolled iron about 4 inches diameter, for supporting signals. These wear away most rapidly between high and low water; at the rate of about an inch in depth in 20 years; in which time the 4-inch bar becomes reduced to a 2-inch one, along that portion of it. Under fresh water especially or under ground, a thin coating of coal-pitch varnish, carefully applied, will protect iron, such as water-pipes, &c., for a long time. See page 655. The sulphuric acid contained in the water from coal mines corrodes iron pipes rapidly. **In the fresh water of canals,** iron boats have continued in service from 20 to 40 years. **Wood remains sound** for centuries under either fresh or salt water, if not exposed to be worn away by the action of currents; or to be destroyed by marine insects.

Sea water weighs from 64 to 64.27 lbs per cubic foot, or say from 1.6 to 1.9 lbs per cubic foot more than fresh water, varying with the locality, and not appreciably with the depth. The excess, over the weight of fresh water, is chiefly common salt. At 64 lbs per cubic foot, 35 cubic feet weigh 2240 lbs. **Sea water freezes** at about 27° Fahr. The ice is fresh; but (especially at low temperatures) brine may be entrapped in the ice.

A teaspoonful of powdered alum, well stirred into a bucket of **dirty water,** will generally purify it sufficiently within a few hours to be drinkable. If a hole 3 or 4 feet deep be dug in the sand of the sea-shore, the infiltrating water will usually be sufficiently fresh for washing with soap; or even for drinking. It is also stated that water may be preserved sweet for many years by placing in the containing vessel 1 ounce of black oxide of manganese for each gallon of water.

It is said that water kept in zinc tanks; or flowing through iron tubes galvanized inside, rapidly becomes poisoned by soluble salts of zinc formed thereby; and it is recommended to coat zinc surfaces with asphalt varnish to prevent this. Yet, in the city of Hartford, Conn, service pipes of iron, galvanized inside and out, were adopted in 1855, at the recommendation of the water commissioners; and have been in use ever since. They are likewise used in Philadelphia and other cities to a considerable extent. In many hotels and other buildings in Boston, the "Seamless Drawn Brass Tube" of the American Tube Works at Boston, has for many years been in use for service pipe; and has given great satisfaction. It is stated that the softest water may be kept in brass vessels for years without any deleterious result.

The action of lead upon some waters (even pure ones) is highly poisonous. The subject, however, is a complicated one. An injurious ingredient may be attended by another which neutralizes its action. Organic matter, whether vegetable or animal, is injurious. Carbonic acid, when not in excess, is harmless.

Ice may be so impure that its water is dangerous to drink.

The popular notion that hot water freezes more quickly than cold, with air at the same temperature, is erroneous.

TIDES.

The tides are those well-known rises and falls of the surface of the sea and of some rivers, caused by the attraction of the sun and moon. There are two rises, floods, or high tides; and two falls, ebbs, or low tides, every 24 hours and 50 minutes (**a lunar day**); making the average of 6 hours 12½ minutes between high and low water. These intervals are, however, **subject to great variations;** as are also the heights of the tides; and this not only at different places, but at the same place. These irregularities are owing to the shape of the coast line, the depth of water, winds, and other causes. *Usually* at new and full moon, or rather a day or two after, (or twice in each lunar month, at intervals of two weeks,) the tides rise higher, and fall lower than at other times; and these are called **spring tides.** Also, one or two days after the moon is in her *quarters*, twice in a lunar month, they both rise and fall less than at other times; and are then called **neap tides.** From neap to spring they rise and fall more daily; and vice versa. The **time of high water** at any place, is generally two or three hours after the moon has passed over either the upper or lower meridian; and is called the **establishment** of that place; because, when this time is established, the time of high water on any other day may be found from it in most cases. The total height of spring tides is *generally* from 1½ to 2 times as great as that of neaps. The great **tidal wave** is merely an *undulation*, unattended by any current, or progressive motion of the particles of water. Each successive high tide occurs about 24 minutes later than the preceding one; and so with the low tides

EVAPORATION AND LEAKAGE.

The amount of evaporation from surfaces of water exposed to the natural effects of the open air, is of course greater in summer than in winter, although it is quite perceptible in even the coldest weather. It is greater in shallow water than in deep, inasmuch as the bottom also becomes heated by the sun. It is greater in running, than in standing water, on much the same principle that it is greater during winds than calms. It is probable that the average daily loss from a reservoir of moderate depth, from evaporation alone, throughout the 3 warmer months of the year, (June, July, August,) rarely exceeds about $\frac{3}{10}$ inch, in any part of the United States. Or $\frac{1}{10}$ inch during the 9 colder months, except in the Southern States. These two averages would give a daily one of .15 inch, or a total annual loss of 55 ins, or 4 ft 7 ins. It probably is 3.5 to 4 ft.

By some trials by the writer, in the tropics, ponds of pure water 8 ft deep, in a stiff retentive clay, and fully exposed to a very hot sun all day, lost during the dry season, precisely 2 ins in 16 days, or ⅛ inch per day, while the evaporation from a glass tumbler was ¼ inch per day. The air in that region is highly charged with moisture, and the dews are heavy. Every day during the trial the thermometer reached from 115° to 125° in the sun.

The total annual evaporation in several parts of England and Scotland is stated to average from 22 to 38 ins, at Paris, 31, Boston, Mass, 32, many places in the U. S. 30 to 36 ins. This last would give a daily average of $\frac{1}{10}$ inch for the whole year. Such statements, however, are of very little value, unless accompanied by memoranda of the circumstances of the case, such as the depth, exposure, size and nature of the vessel, pond, &c, which contains the water, &c. Sometimes the total annual evaporation from a district of country exceeds the rain fall, and vice versa.

On canals, reservoirs, &c, it is usual to combine the loss by evaporation, with that by filtration. The last is that which soaks into the earth; and of which some portion passes entirely through the banks, (when in embankt,) and if in very small quantity, may be dried up by the sun and air as fast as it reaches the outside, so as not to exhibit itself as water, but if in greater quantity, it becomes apparent, as *leakage*.

E. H. Gill, C E. states the average evaporation and filtration on the Sandy and Beaver canal, Ohio, (38 ft wide at water surface, 26 ft at bottom, and 4 ft deep,) to be but 13 cub ft per mile per minute, *in a dry season*. Here the exposed water surf in one mile is 200640 sq ft, and in order, with this surf, to lose 13 cub ft per min, or 18720 cub ft per day of 24 hours, the quantity lost must be $\frac{18720}{200640}$ = .0933 ft, = 1⅛ inch in depth per day. Moreover, one mile of the canal contains 675840 cub ft; therefore the number of days reqd for the combined evaporation and filtration to amount to as much as all the water in the canal, is $\frac{675840}{18720}$ = 36 days. Observations in warm weather on a 22 mile reach of the Chenango canal, N York, (40, 28, and 4 ft,) gave 65⅓ cub ft per mile per min; or 5 times as much as in the preceding case. This rate would empty the canal in about 8 days. Besides this there was an excessive leakage at the gates of a lock, (of only 5⅓ ft lift,) of 479 cub ft per min = 22 cub ft per mile per min; and at aqueducts, and waste weirs, others amounting to 19 cub ft per mile per min. The leakage at other locks with lifts of 8 ft, or less, did not *exceed* about 350 cub ft per min at each. On other canals, it has been found to be from 50, to 500 ft per min. On the Chesapeake and Ohio canal, (where 50, 32, and 6 ft,) Mr. Fisk, C E estimated the loss by evap and filtration in 2 weeks of warm weather, to be equal to all the water in the canal. **Professor Rankine assumes 2 ins per day, for leakage of canal bed, and evaporation, on English canals.** J B Jervis, C E, estimated the loss from evap, filtration, and leakage through lock-gates, on the original Erie canal, (40, 28, and 4 ft,) at 100 cub ft per mile per min, or 144000 cub ft per day. The water surf in a mile is 211200 sq ft; therefore, the daily loss would be equal to a depth of $\frac{144000}{211200}$ = .682 ft, = say 8⅛ ins.

On the Delaware division of the Pennsylvania canals, when the supply is temporarily shut off from any long reach, the water falls from 4 to 8 ins per day. The filtration will of course be much greater on embankts, than in cuts. In some of our canals, the depth at high embankts becomes quite considerable, the earth, from motives of economy not being filled in level under the bottom of the canal, but merely left to form its own natural slopes. At one spot at least, on the Ches and Ohio canal, where one side is a natural face of vertical rock, this depth is 40 ft. Such depths increase the leakage very greatly; especially when, as is frequently the case the embankts are not puddled, and the practice is not to be commended, for other reasons also.

The total average loss from reservoirs of moderate depths, in case the earthen dams be constructed with proper care, and well settled by time, will not exceed about from ½ to 1 inch per day, but in new ones, it will usually be considerably greater.

The loss from ditches, or channels of small area, is much greater than that from navigable canals, so that long canal feeders usually deliver but a small proportion of the water which enters them at their heads.

MECHANICS. FORCE IN RIGID BODIES.

In the following pages we endeavor to make clear a few elementary principles of Mechanics The opening articles are devoted chiefly to the subject of matter *in motion;* for, while an acquaintance with this is perhaps not absolutely required in obtaining a *working* knowledge of those principles of Statics which enter so largely into the computations of the civil engineer, yet it must be an important aid to their intelligent appreciation.

Art. 1 (a). Mechanics may be defined as that branch of science which treats of the effects of force upon matter.

This broad definition of the word "Mechanics" includes hydrostatics, hydraulics, pneumatics etc., if not also electricity, optics, acoustics, and indeed all branches of physics; but we shall here confine ourselves chiefly to the consideration of the action of extraneous forces upon bodies supposed to be *rigid* or incapable of change of shape

(b) Mechanics is divided into two branches, namely:

Kinematics; or the study of the *motions* of bodies, without reference to the *causes* of motion; and

Dynamics, or the study of force and its effects.

The latter is sub-divided into

Kinetics; which treats of the relations between force and *motion;* and

Statics; which considers those special, but very numerous cases, where *equal and opposite* forces counteract each other and thus destroy each other's motions.

Art 2 (a). Matter, or substance, may be defined as whatever occupies space; as meta , stone, wood, water, air, steam, gas, etc.

(b) A body is any portion of matter which is either more or less completely separated in fact from all other matter, or which we take into consideration by itself and as if it were so separated. Thus, a stone is a body, whether it be falling through the air or lying detached upon the ground, or built up into a wall. Also, the wall is a body; or, if we wish, we may consider any portion of the wall as any particular cubic foot or inch in it, as a body. The earth and the other planets are bodies and their smallest atoms are bodies.

A train of cars may be regarded as a body; as may also each car, each wheel or axle or other part of the car, each passenger, etc., etc.

Similarly, the ocean is a body, or we may take as a body any portion of it at pleasure, such as a cubic foot, a certain bay, a drop, etc

(c) But in what follows we shall (as already stated) consider chiefly *rigid* bodies; *i. e.* bodies which undergo no change in *shape*, such as by being crushed or stretched or pulled apart, or penetrated by another body. All actual bodies are of course more or less subject to some such changes of shape; *i. e*, no body is *in fact* absolutely rigid; but we may properly, for convenience, suppose such bodies to exist because many bodies are so nearly rigid that under ordinary circumstances they undergo little or no change of shape, and because such change as does occur may be considered under the distinct head of Strength of Materials

(d) But while bodies are thus to be regarded as incapable of change of *form*, it is equally important that we regard them as *susceptible* to change of *position* as *wholes*. Thus, they may be upset or turned around horizontally or in any other direction, or moved along in any straight or curved line, with or without turning around a point within themselves. In short they are capable of *motion*, as *wholes*.

Art. 3 (a). Motion of a body is change of its position in relation to another body or to some real or imaginary point, which (for convenience) we *regard* as fixed, or at rest. Thus, while a stone falls from a roof to the ground, its position, relatively to the roof is constantly changing, as is also that relatively to the ground and that relatively to any given point in the wall; and we say that the stone is *in motion relatively to either of those bodies*, or to any point in them. But if two stones, A and B, fall from the roof at the same instant and reach the ground at the same (subsequent) instant, we say that although each moves, relatively to roof and ground, yet they have *no motion relatively to each other*; or, they are *at rest* relatively to each other; for their position in regard to each other does not change; *i. e.*, in whatever direction and at whatever distance stone A may be from stone B at the time of starting, it remains in that same direction, and at that same distance from B during the whole time of the fall. Similarly, the roof, the wall and the ground are at rest relatively to each other, yet they are in motion relatively to a falling stone. They are also in motion relatively to the sun owing to the earth's daily rotation about its axis, and its annual movement around the sun.

(**b**) If a train-man walks toward the rear along the top of a freight train just as fast as the train moves forward he is in *motion* relatively to the *train*; but, as a whole, he is at *rest* relatively to *buildings*, etc. near by; for a spectator, standing at a little distance from the track, sees him continually opposite the same part of such building etc. If the man on the train now stops walking, he comes to *rest* relatively to the *train*, but at the same time comes into *motion* relatively to the surrounding *buildings*, etc., for the spectator sees him begin to move along with the train.

(**c**) Since we know of no absolutely fixed point in space we cannot say, of any body, what its *absolute* motion is. Consequently we do not know of such a thing as absolute *rest*, and are safe in saying that *all* bodies are in motion.

Art. 4 (a). The **velocity** of a moving body is its *rate* of motion. A body (as a railroad train) is said to move with **uniform velocity**, or **constant velocity**, when the *distances* moved over in *equal times* are *equal to each other*, no matter how small those times may be taken.

(**b**) The **velocity is expressed** by stating the *distance* passed over *during some given time*, or which *would* be passed over during that time if the uniform motion continued so long. Thus, if a railroad train, moving with constant velocity, passes over 10 miles in half an hour, we may say that its velocity, during that time, is (*i. e.*, that it moves *at the rate* of) 20 miles per hour or 105,600 feet per hour, or 1760 feet per minute, or 29$\frac{1}{3}$ feet per second. Or, we may, if desirable, say that it moves at the rate of 10 miles in *half* an hour or 88 feet in *three* seconds, etc.; but it is generally more convenient to state the distance passed over in a *unit* of time, as in *one* day *one* hour, *one* second, etc.

(**c**) If, of two trains, A and B, moving with constant velocity,

A moves 10 miles in half an hour,
B moves 10 miles in quarter of an hour,

then the velocities are,

A, 20 miles per hour,
B, 40 miles per hour.

In other words, the velocity of a body (which may be defined as the *distance* passed over in a given *time*) is *inversely* as the *time* required to pass over a given *distance*.

(**d**) By **unit velocity** is meant that velocity which, by common consent is taken as equal to *unity* or *one*. Where English measures are used, the unit velocity generally adopted in the study of Mechanics is 1 foot per second.

(**e**) When we say that a body has a velocity of 20 miles per hour, or 10 feet per second, etc. we do not imply that it will necessarily travel 20 miles, or 10 feet, etc.; for it may not have sufficient time for that. We mean merely that it is traveling at the *rate* of 20 miles per hour, or 10 feet per second, etc.; so that *if it continued* to move at that same rate for an hour, or a second, etc., it would travel 20 miles, or 10 feet etc.

(**f**) When velocity *increases* it is said to be **accelerated.** When it *decreases*, it is said to be **retarded.** If the acceleration or retardation is in exact proportion to the time; that is, when during any and every equal interval of time, the same degree of change takes place, it is *uniformly* accelerated, or retarded. When otherwise, the words *variable* and *variably* are used.

(**g**) A body may have at the same time, **two or more independent velocities** requiring to be considered. For instance, a ball fired vertically upward from a

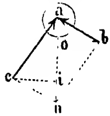
gun, and then falling again to the earth, has, during the whole time of its rise and fall, (1st) the *uniform upward* velocity with which it leaves the muzzle, and (2nd) the continually *accelerated downward* velocity given to it by gravity, which acts upon it during the whole time. Its *resultant* (or apparent) velocity at any moment is the *difference* between these two.

Thus, immediately after leaving the gun, the downward velocity given by gravity is very small, and the resultant velocity is therefore upward and very nearly equal to the whole upward velocity due to the powder. But after awhile the downward velocity (by constantly increasing) becomes equal to the upward velocity; *i. e.*, their difference, or the resultant velocity, becomes *nothing;* the ball at that instant stands still; but its downward velocity continues to increase, and immediately becomes a little greater than the upward velocity, then greater and greater, until the ball strikes the ground. At that instant its resultant velocity is

$$= \left\{ \begin{array}{c} \text{the downward velocity which it would} \\ \text{have acquired by falling } \textit{during the} \\ \textit{whole time of its rise and fall.} \end{array} \right\} - \left\{ \begin{array}{c} \text{the uniform upward} \\ \text{velocity given by the} \\ \text{powder.} \end{array} \right.$$

We have here neglected the resistance of the air, which of course retards both the ascent and the descent of the ball.

(**h**) As a further illustration, regard *a b n c* as a raft drifting in the direction *c a* or *n b*. A man on the raft walks with uniform velocity from corner *n* to corner *c* while the raft drifts (with a uniform velocity a little greater than that of the man) through the distance *n b*. Therefore, when the man reaches corner *c*, that corner has moved to the point which, when he started, was occupied by *a*. The man's resultant motion, relatively to the bed of the river or to a point on shore, has therefore been *n a*. His motion at right angles to *n a*, due to his walking, is *i c*, but that due to the drifting of the raft is *o b*. These two are equal and opposite. Hence his *resultant* motion *at right angles* to *n a* is nothing; he does not move from the line *n a*. His walking moves him through a distance equal to *n i*, in the direction *n a:* and the drifting through a distance equal to *i a*, and the sum of these two is *n a*.



(**i**) All the motions which we see given to bodies are but *changes* in their unknown *absolute* motions. For convenience, we may confine our attention to some one or more of these changes, neglecting others.

Thus, in the case of the ball fired upward from a gun (see (*g*) above) we may neglect its uniform upward motion and consider only its constantly accelerated downward motion under the action of gravity, or, as is more usual we may consider only the *resultant* or *apparent* motion, which is first upward and then downward. In both cases we neglect the motions of the ball caused by the several motions of the earth in space.

Art. 5 (a). Force, the cause of change of motion. Suppose a perfectly smooth ball resting upon a perfectly hard, frictionless and level surface, and suppose the resistance of the air to be removed. In order to merely *move* the ball horizontally (*i. e.*, to set it in motion—to change its state of motion) some *force* must act upon it. Or, if such a ball were already in motion, we could not retard, or hasten it, or turn it from its path without exerting force upon it. For, as stated in **Newton's first law of motion, "every body continues in its state** of rest or of motion in a straight line, except in so far as it may be compelled by impressed forces to change that state." On the other hand, if a force acts upon a body, the motion of the body must undergo change.

(**b**) **Force is an action between two bodies, tending either to separate them or to bring them closer together.** For instance, when a stone falls to the ground, we explain the fact by saying that a force (the attraction of gravitation) tends to draw the earth and the stone together.

Magnetic and electric attraction, and the cohesive force between the particles of a body, are other instances of *attractive* force.

(**c**) **Force applied by contact.** In practice we apply force to a body (B) by causing contact between it and another body (A) which has a tendency to motion toward B. A *repulsive* force is thus called into action between the two bodies (in some way which we cannot understand), and this force pushes B forward (or in the

direction of A's tendency to move) and pushes A backward, thus *diminishing* its forward tendency *

If, for instance, a stone be laid upon the ground, it tends to move downward, but does not do so, because a repulsive force pushes it and the earth apart just as hard as the force of gravity tends to draw them together.

Similarly, when we attempt to lift a moderate weight with our hand, we do so by giving the hand a tendency to move upward. If the hand slips from the weight, this tendency moves the hand rapidly upward before our will force can check it. But otherwise, the repulsive force, generated by contact between the hand (tending upward) and the weight, moves the latter upward in spite of the force of gravity, and pushes the hand downward, depriving it of much of the upward velocity which it would otherwise have. It is perhaps chiefly from the **effort,** of which we are conscious in such cases, that we derive our notions of **"force."**

When a moving billiard ball, A, strikes another one, B, at rest, the tendency of A to continue moving forward is resisted by a repulsive force acting between it and B. This force pushes B forward, and A backward, retarding its former velocity. As explained in Art. 23 (*a*), the repulsive force does not exist in either body until the two meet.

(d) The repulsive force thus generated by contact between two bodies, continues to act only so long as they remain in contact, and only so long as they tend (from some extraneous cause) to come closer together.

(e) Force acts either as a pull or as a push. Thus, when a weight is suspended by a hook at the end of a rope gravity *pulls* the weight downward, the weight *pushes* the hook, and the hook *pulls* the rope, each of these actions being accompanied, of course, by its corresponding and opposite "reaction." When two bodies collide, each pushes the other, generally for a very short time.

(f) Equality of action and reaction. A force always exerts itself *equally* upon the two bodies between which it acts. Thus, the force (or attraction) of gravitation, acting between the earth and a stone, draws the earth upward just as hard as it draws the stone downward; and the repulsive force, acting between a table and a stone resting upon it, pushes the table and the earth downward just as hard as it pushes the stone upward This is the fact expressed by **Newton's third law of motion,** that "to every action there is always an equal and contrary reaction" For measures of force, see Arts. 11, 12, 13.

If a cannon ball in its flight cuts a leaf from a tree, we say that the *leaf* has reacted against the *ball* with precisely the same force with which the ball acted against the leaf. That degree of force was sufficient to cut off a leaf, but not to arrest the ball. A ship of war, in running against a canoe, or the fist of a pugilist striking his opponent in the face, receives as violent a blow as it gives; but the same blow that will upset or sink a canoe, will not *appreciably* affect the motion of a ship, and the blow which may seriously damage a nose, mouth, or eyes, may have no such effect upon hard knuckles.

The resistance which an abutment opposes to the pressure of an arch; or a retaining-wall to the pressure of the earth behind it, is no greater than those pressures themselves; but the abutment and the wall are, for the sake of safety, made *capable* of sustaining much greater pressures, in case accidental circumstances should produce such.

(g) In most practical cases **we have to consider only one** of the two bodies between which a force acts. Hence, for convenience, we commonly speak as if the force were divided into *two* equal and opposite forces one for each of the two bodies, and confine our attention to *one* of the bodies and the force acting upon it, neglecting the other. Thus we may speak of the force of steam in an engine as acting upon the *piston*, and neglect its equal and opposite pressure against the head of the cylinder

(h) That point of a body to which, theoretically, a force is applied, is called the **point of application.** In practice we cannot apply force to a *point*, according to the scientific meaning of that word; but have to apply it distributed over an appreciable *area* (sometimes very large) of the surface of the body.

*** We ordinarily express all this by saying simply that A pushes B forward, and this is sufficiently exact for practical purposes; but it is well to recognize that it is merely a convenient expression and does not fully state the facts, and that every force *necessarily* consists of *two* equal and opposite pulls or pushes exerted between two bodies.**

For the present we shall assume that the line of action of the force passes through the center of gravity of the body and forms a right angle with the surface at the point of application.

Art. 7 (a). Acceleration. When an unresisted force, acting upon a body, sets it in motion (*i. e.*, gives it velocity) in the direction of the force, this velocity *increases* as the force continues to act; each equal interval of time (if the force remains constant) bringing its own equal increase of velocity.

Thus, if a stone be let fall, the force of gravity gives to it, in the first inconceivably short interval of time, a small velocity downward. In the next equal interval of time, it adds a second equal velocity, and so on, so that at the end of the second interval the velocity of the stone is twice as great, at the end of the third interval three times as great, as at the end of the first one, and so on. We may divide the time into as small equal intervals as we please. In each such interval the constant* force of gravity gives to the stone an equal increase of velocity.

Such increase of velocity is called acceleration.† When a body is thrown vertically *upward*, the downward acceleration of gravity appears as a *retardation* of the upward motion. When a force thus acts *against* the motion under consideration, its acceleration is called *negative*.

Art. 8 (a). The rate of acceleration† is the acceleration which takes place *in a given time*, as one second.

(b) The **unit rate of acceleration** is that which adds unit of velocity in a unit of time; or, where English measures are used, one foot per second *per second*.

(c) For a *given rate* of acceleration, the *total* accelerations are of course proportional to the *times* during which the velocity increases at that rate.

Art 9 (a). Laws of acceleration. Suppose two blocks of iron, one (which we will call A) twice as large as the other (*a*), placed each upon a perfectly frictionless and horizontal plane, so that in moving them horizontally we are opposed by no force tending to hold them still. Now apply to each block, through a spring balance, a pull such as will keep the pointer of each balance always at the same mark, as, for instance, constantly at 2 in both balances. We thus have equal forces acting upon unequal masses.‡ Here the rate of acceleration of *a* is double that of A; for **when the forces are equal the rates of acceleration are inversely as the masses.**

In other words, in one second (or in any other given time) the small block of iron, *a*, will acquire twice the increase of velocity that A (twice as large) will acquire so that if both blocks start at the same time from a state of rest, the smaller one, *a*, will have, at the end of any given time, twice the *velocity* of A, which has twice its mass.

(b) Again, let the two masses A and *a*, be equal, but let the *force exerted* upon *a* be twice that exerted upon A. Then the rate of acceleration of *a* will (as before) be twice that of A; for, **when the masses are equal, the rates of acceleration are directly as the forces.**

(c) We thus arrive at the principle that, in any case, **the rate of acceleration is directly proportional to the force and inversely proportional to the mass.**

---

*We here speak of the force of gravity, exerted in a given place, as constant, because it is so for all practical purposes. Strictly speaking, it increases a very little as the stone approaches the earth.

†Since the *rate* of acceleration is generally of greater consequence, in Mechanics, than the *total* acceleration, or the "acceleration" proper, scientific writers (for the sake of brevity) use the term "acceleration" to denote that *rate*, and the term "*total* acceleration" to denote the total increase or decrease of velocity occurring during any given time. Thus, the *rate* of acceleration of gravity (about 32.2 ft. per second per second) is called, simply the "acceleration of gravity." As we shall not have to use either expression very frequently we shall generally to avoid misapprehension, give to each idea its *full* name; thus, "total acceleration" for the *whole change of velocity* in a given case, and "rate of acceleration" for the *rate* of that change.

‡The mass of a body is the quantity of matter that it contains.

(d) Hence, if we make the two forces proportional to the two masses, the rates of acceleration will be equal; or, **for a given rate of acceleration, the forces must be directly as the masses.**

(e) Hence, also, a greater force is required to impart a given velocity to a given body in a short time than to impart the same velocity in a longer time. For instance, the forward coupling links of a long train of cars would snap instantly under a pull sufficient to give to the train in two seconds a velocity of twenty miles per hour, supposing a sufficiently powerful locomotive to exist. In many such cases, therefore, we have to be contented with a slow, instead of a rapid acceleration.

A string may safely sustain a weight of one pound suspended from our hand. If we wish to impart a great upward velocity to the weight *in a very short time*, we evidently can do so only by exerting upon it a great force; in other words, by jerking the string violently upward. But if the string has not tensile strength sufficient to transmit this force from our hand to the weight, it will break. We might safely give to the weight the desired velocity by applying a *less force* during a *longer time*.

(f) When a stone falls, the *force* pulling the earth upward is (as remarked above) equal to that which pulls the stone downward, but the *mass* of the earth is so vastly greater than that of the stone that its motion is totally imperceptible to us, and would still be so, even if it were not counteracted by motions in other directions in other parts of the earth. Hence we are *practically*, though *not absolutely*, right when we say that the earth remains at rest while the stone falls.

(g) But in the case of the two billiard balls (Art. 5 *c* p. 333), we can clearly see the result of the action of the force upon each of the two bodies; for the second ball, B, which was at rest, now moves forward, while the forward velocity of the first one, A, is diminished or destroyed, its backward motion thus appearing as a *retardation* of its *forward* motion. And, (since the same force acts upon both balls)

$$\begin{array}{c}\text{mass}\\\text{of A}\end{array} : \begin{array}{c}\text{mass}\\\text{of B}\end{array} :: \begin{array}{c}\text{rate of acceleration}\\\text{of B}\end{array} : \begin{array}{c}\text{rate of negative acceleration}\\\text{of A}\end{array}$$

or (since the force acts for the same time upon both balls)

$$\begin{array}{c}\text{mass}\\\text{of A}\end{array} : \begin{array}{c}\text{mass}\\\text{of B}\end{array} :: \begin{array}{c}\text{forward velocity}\\\text{of B}\end{array} : \begin{array}{c}\text{loss of forward velocity}\\\text{of A}\end{array}$$

(h) Remark. A man cannot *lift* a weight of 20 tons; but if it be placed upon proper friction rollers, he can *move* it horizontally, as we see in some drawbridges, turntables, &c.; and if friction and the resistance of the air could be entirely removed, he could move it by a single breath; and it would continue to move forever after the force of the breath had ceased to act upon it. It would, however, move very slowly, because the force of the single breath would have to diffuse itself among 20 tons of matter. He can move it, if it be placed in a suitable vessel in water, or if suspended from a long rope. A powerful locomotive that may move 2000 tons, cannot lift 10 tons vertically.

If we imagine two bodies, each as large and heavy as the earth, to be precisely balanced in a pair of scales without friction, a single grain of sand added to either scale-pan, would give motion to both bodies.

Art. 10 (a). The constant force of gravity is a uniformly accelerating force when it acts upon a body falling freely; for it then increases the velocity at the uniform rate of .322 of a foot per second during every hundredth part of a second, or 32.2 feet per second in every second. Also when it acts upon a body moving down an inclined plane; although in this case the increase is not so rapid, because it is caused by only a part of the gravity, while another part presses the body to the plane, and a third part overcomes the friction. It is a uniformly retarding force, upon a body thrown vertically upward; for no matter what may be the velocity of the body when projected upward, it will be diminished .322 of a foot per second in each hundredth part of a second during its rise, or 32.2 feet per second during each entire second. At least, such would be the case were it not for the varying resistance of the air at different velocities. It is a uniformly straining force when it causes a body at rest, to press upon another body; or to pull upon a string by which it is suspended. The foregoing expressions, like those of momentum, strain, push, pull, lift, work, &c., do not indicate different *kinds* of force; but merely different kinds of *effects* produced by the one grand principle, force.

(b) The above 32.2 ft per second *per second* is called the **acceleration of gravity**, and customarily denoted by a small **g**; or, more correctly speaking, since the acceleration is not precisely the same at all parts of the earth, g denotes the acceleration, whatever it may be, at any particular place.

Art. 11 (a). Relation between force and mass. The mass of a body is the quantity of matter which it contains. *One* cubic foot of water has *twice* as great a mass as *half* a cubic foot of water, but a *less* mass than *one* cubic foot of iron. Thus, the *size* of a body is a measure of mass between bodies of the *same* material, but not between bodies of *different* materials.

(b) When bodies are allowed to fall freely in a vacuum at a given place, they are found to acquire equal velocities in any given time, of whatever different materials they may be composed. From this we know (Art. 9 (*d*), p. 335), that the *forces* moving them downward, viz.: their respective *weights* at that place, must be proportional to their *masses*.

Thus, *in any given place*, the *weight* of a body is a perfect measure of its *mass*. But the *weight* of a given body *changes* when the body is moved from one level above the sea to another, or from one latitude to another; while the *mass* of the body of course remains *the same* in all places. Thus, a piece of iron which weighs a pound at the level of the sea, will weigh *less* than a pound by a spring balance, upon the top of a mountain close by, because the attraction between the earth and a given mass diminishes when the latter recedes from the earth's center. Or if the piece of iron weighs one pound near the North or South Pole, it will, for the same reason, weigh *less* than a pound by a spring balance if weighed nearer to the equator and at the same level above the sea.

The difference in the weight of a body in different localities is so slight as to be of no account in questions of ordinary practical Mechanics;* but scientific exactness requires a measure of mass which will give the same expression for the quantity of matter in a given body, wherever it may be; and, since weighing is a very *convenient* way of arriving at the quantity of matter in a body, it is desirable that we should still be able to express the mass in terms of the weight. Now, when a given body is carried to a higher level, or to a lower latitude, its loss of weight is simply a decrease in the *force* with which gravity draws it downward, and this same decrease also causes a decrease of the *velocity* which the body acquires in falling during any given time. The change in velocity, by Art. 9 (*b*), p. 334, is necessarily proportional to the change in weight.

Therefore, if the weight of a body at any place be divided by the velocity which gravity imparts in one second at the same place (and called **g**, or the *acceleration of gravity* for that place), the *quotient* will be the same at all places, and therefore serves as an invariable measure of the mass.

(c) By common consent, the **unit of mass**, in scientific Mechanics, is said to be that quantity of matter to which a *unit* of force can give unit rate of acceleration. This unit rate, in countries where English measures are used, is one foot per second, per second. It remains then to adjust the units of *force* and of *mass*. Two methods (an old and a new one) are in use for doing this. We shall refer to them here as methods A and B respectively.

(d) In method A, still generally used in questions of *statics*, the **unit of force** is fixed as that force which is equal to the *weight of one pound* in a certain place; *i. e.*, the force with which the earth at that place attracts a certain standard piece of platinum called a pound; and the unit of *mass* is not this standard piece of metal, but, as stated in (c), that mass to which this unit force of one pound gives, in one second, a velocity of one foot per second. Now the one pound attraction of the earth upon a mass of *one pound* will (Art. 1, p. 330) in one second give to that mass a velocity = g or about 32 feet per second; and (Art. 9 (*a*), p. 334), for a given force the masses are inversely as the velocities imparted in a given time. Therefore, to give in one second a velocity of only *one* foot per second (instead of g or about 32) the one pound unit of force would have to act upon a mass g times (or about 32 times) that which weighs one pound.

This could be accomplished, with an Atwood's machine, Art. 16 (*c*), p. 339, by making the two equal weights each = 15½ lbs. and the third weight = 1 lb.

---

*The greatest discrepancy that can occur at various heights and latitudes, by adopting weight as the measure of quantity, would not be likely to *exceed* 1 in 300; or, under ordinary circumstances, 1 in 1000.

By method A, therefore, the *unit* of mass is g times (or about 32 times) the mass of the standard piece of metal called a pound; *i. e.*, a body containing one such unit of mass weighs g lbs. or about 32 lbs.; or, **by method A,**

$$\text{the } \textit{weight} \text{ of any given body in lbs.} = g \times \text{the } \textit{mass} \text{ of the body, in units of mass.}$$

Or,

$$\text{the } \textit{mass} \text{ of a body, in units of mass} = \frac{\text{the weight of the body, in pounds}}{g}$$

For instance:

in a body weighing	the mass is about
½ pound	$\frac{1}{64}$ unit of mass
1 "	$\frac{1}{32}$ " "
2 "	$\frac{1}{16}$ " "
32 "	1 " "
64 "	2 " "

It has been suggested to call this unit of mass a "Matt."

(e) **In method B,** the *mass* of the standard pound piece of platinum is taken as the **unit of mass** and is called a **pound;** and the force which will give to it in one second a velocity of one foot per second is taken as the unit of *force*. This small unit of force is called a **poundal.** In order that it may in one second give to the mass of one pound a velocity of only one foot per second, it must (by Art. 9 b), be $\frac{1}{g}$ (or about $\frac{1}{32}$) of the *weight* of said pound mass.

Hence, **by method B,**

$$\text{the } \textit{mass} \text{ of any given body, in } \textit{pounds} = \frac{\text{the } \textit{weight} \text{ of the body in } \textit{poundals}}{g}$$

and

$$\text{the } \textit{weight} \text{ of a body, in } \textit{poundals} = g \times \text{the } \textit{mass} \text{ of the body in } \textit{pounds}.$$

For instance:

in a body weighing	the mass of the body is about
½ poundal = $\frac{1}{64}$ pound	$\frac{1}{64}$ pound
1 " = $\frac{1}{32}$ "	$\frac{1}{32}$ "
2 " = $\frac{1}{16}$ "	$\frac{1}{16}$ "
32 " = 1 "	1 "
64 " = 2 "	2 "

(f) In the **C. G. S. (centimeter-gram-second) system,** a force of **1 dyne,** acting, for **1 second,** upon a mass of **1 gram,** gives it a velocity of **1 centimeter per second.** See also Art. 17 (b), p 341.

Art. 12 (a). The product, force × time, is called **impulse.** The product, mass × velocity, is called **momentum.**

According to **Newton's second law of motion,**

$$\left.\begin{matrix}\text{Force} \times \text{time} = \text{mass} \times \text{velocity} \\ \text{or impulse} = \text{momentum*}\end{matrix}\right\} \text{ or } f\,t = m\,v \quad \ldots\ldots\ldots (1)$$

$$\text{Force} = \frac{\text{impulse}}{\text{time}} = \frac{\text{mass} \times \text{velocity}}{\text{time}} = \frac{\text{momentum}}{\text{time}}; \text{ or } f = \frac{m\,v}{t} \quad \ldots (2)$$

$$\text{Time} = \frac{\text{impulse}}{\text{force}} = \frac{\text{mass} \times \text{velocity}}{\text{force}} = \frac{\text{momentum}}{\text{force}}; \text{ or } t = \frac{m\,v}{f} \quad \ldots (3)$$

$$\text{Mass} = \frac{\text{momentum}}{\text{velocity}} = \frac{\text{force} \times \text{time}}{\text{velocity}} = \frac{\text{impulse}}{\text{velocity}}; \text{ or } m = \frac{f\,t}{v} \quad \ldots (4)$$

$$\text{Velocity} = \frac{\text{momentum}}{\text{mass}} = \frac{\text{force} \times \text{time}}{\text{mass}} = \frac{\text{impulse}}{\text{mass}}, \text{ or } v = \frac{f\,t}{m} \quad \ldots (5)$$

---

*Strictly, impulse = *change* of momentum; but we here assume that the change is from or to a state of *rest*, so that momentum = change of momentum.

Let a force, *f*, of 320 poundals (= say 10 pounds *) act, for 3 seconds, upon a mass, *m*, of 5 lbs. (= say $\frac{5}{32}$ matt). Here the force, *f*, is twice the weight of the mass, *m*. Hence the acceleration will be twice that of gravity, *i. e.*, say 64 ft per sec per sec; and the velocity, generated in 3 secs, will be 3 × 64 = 192 ft per sec; and we have, from Eq (1):

$$\underbrace{f \cdot t}_{\text{Force} \times \text{time} = \text{impulse}} = \underbrace{m \cdot v}_{\text{mass} \times \text{velocity} = \text{momentum}}$$

Force	×	time	=	impulse	=	mass	×	velocity	=	momentum
320 pdl	×	3 sec	=	960 pdl-sec	=	5 lbs.	×	192 ft/sec	=	960 ft-lb/sec
10 pd	×	3 sec	=	30 pd-sec	=	$\frac{5}{32}$ matt	×	192 ft/sec	=	30 ft-matt/sec

From Eq (2) we see that **force = time rate of change of momentum.** Hence the momentum of a body, moving with a given velocity, is numerically equal to that *force* which, *in unit time*, can produce or destroy that velocity in that body. Thus, forces are proportional to the momentums which they can produce (or destroy) in a given time; or, in a given time, equal forces produce (or destroy) equal momentums. Therefore a force must always produce equal and opposite changes of momentum in the two bodies between which it acts. See Art. 5 (b).

If a force, *f*, whose *amount* is 10 poundals, act upon a mass, *m*, of 5 lbs,* its **intensity** is $\frac{10}{5}$ = 2 poundals per lb.* A force of given *intensity* will always produce its proper rate of *acceleration* †, or time rate of change of velocity. Thus:

a force intensity of 1 pdl per lb* produces an accel., *a*, of 1 ft/sec/sec.
" " " " 2 " " " " " " " " 2 "
" " " " g " " " " " " " " g "

The intensity (or acceleration) of gravity, or the acceleration produced, in any mass, by its *weight*, is called **g**, and at sea level is about 32.2 feet, or 981 centimeters, per second per second. See p 348.

Art. 13 (a). A force is commonly measured by ascertaining the amount of some other force which it can counteract. Thus, a spring balance gives, by its scale, the amount of the tension, in the spring, which just counterbalances the weight of the suspended mass. Thus, **forces are conveniently expressed by weights.**

A force may be constant, as that of gravity between the earth and a stone resting upon it. **It may vary regularly,** like the pressure of air compressed by a piston moving with constant velocity, or **it may vary irregularly,** as where the motion of such a piston is irregular. We shall deal only with forces supposed to be *constant.*

Art. 14 (a). Density. The *densities* of materials are proportional to the *masses* contained in a given *volume*, as a cubic inch; or *inversely* as the *volume* required to contain a given *mass*. Or, since the weights at a given place are proportional to the masses, the densities are proportional to the weights per unit of volume (or "specific gravities") of the materials Thus, a body weighing 100 lbs. per cubic foot is twice as dense as one weighing only 50 lbs. per cubic foot at the same place.

Art. 15 (a). Inertia. The inability of matter to set itself in motion, or to change the rate or direction of its motion, is called its inertia, or inertness. When we say that a certain body has twice the inertia (inertness) of another one, we mean that twice the *force* is required to give it an equal rate of acceleration; and that, since all force (Art. 5 *f*) acts equally in both directions, we experience twice as great a *reaction* (or so-called "resistance") from the larger body as from the smaller one. The "inertia" of a body is therefore a measure of the *force* required to produce in it a given rate of acceleration; or, which is the same thing, it is a measure of the *mass* of the body. We may therefore consider "inertia" and "mass" as identical.

(b) What is called the "resistance of inertia" of a body, is simply the reaction (*i. e.*, one of the two equal and opposite actions) of whatever force we apply to the body. Hence, its amount depends not only upon the mass of the body, but also upon the rate of acceleration which we choose to

* In order to distinguish between the pound of *mass* and the pound of *force* (*weight* of a pound of mass at sea level), we here use "pound" or "pnd" or "pd" for the pound of *force*, and "lb" for the pound of *mass*, "pdl" for poundal.

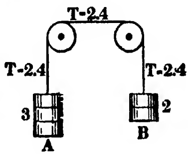
† See foot-note †, p 334.

give to it. Therefore we cannot tell, from the mass or weight of a body alone, what its "resistance of inertia" in any given case will be.

Art. 16 (a). Forces in opposite directions. When two equal and opposite forces act upon a body at the same time, and in the same straight line, we say that they destroy each other's tendencies to move the body, and it remains at rest. If two *unequal* forces thus act in opposition, the smaller force and an equal portion of the greater one are said to counteract each other in the same way, but the remainder of the greater force, acting as an unbalanced or unresisted force, moves the body in its own direction, as it would do if it were the only force acting upon it.

Thus, when we move bodies, in practice, we encounter not only the "resistance of inertia" (*i. e.*, we not only have to exert force in order to move inert matter), but we are also opposed by other *forces*, acting against us, as friction, the resistance of the air, and, often, all or a part of the *weight* of the body. By "resistances," in the following, we mean such resisting *forces*, and do not include in the term the "resistance of *inertia*."

(**b**) If separated, the two bodies, A and B, of 3 lbs and 2 lbs respectively, would fall with equal accelerations = g; each unit, $\frac{W}{g}$, of mass being acted upon by its own weight, W. But, connected as they are, A will move downward, and B upward, with an acceleration = only $\frac{g}{5}$; for now an unbalanced force of only 3 — 2 = 1 lb must give acceleration to a mass of $\frac{3+2}{g} = \frac{5}{g}$. But, to give to a mass, B, of $\frac{2}{g}$, an accel of $\frac{g}{5}$, requires a force of $\frac{2}{g} \cdot \frac{g}{5} = \frac{2}{5}$ lb = 0.4 lb. This, plus 2 lbs (required to balance the *weight* of B) is the tension, 2.4 lbs existing throughout the cord. Exerted at A, this tension balances 2.4 of the 3 lbs weight of A. The remainder (3 — 2.4 = 0.6 lb) of the weight, acting downward upon the mass, $\frac{3}{g}$, of A, gives to it the required acceleration of $\frac{g}{5}$; for here $\frac{\text{force}}{\text{mass}} = 0.6 \div \frac{3}{g} = \frac{0.6\,g}{3} = 0.2\,g = \frac{g}{5}$.



Or we may regard the total tension, 2.4 lbs, in the cord at A, as acting upon A and giving to it a *negative* or *upward* acceleration of $2.4 \div \frac{3}{g} = 0.8$ g, which, deducted from g (the acceleration which A would otherwise have) leaves

$$\text{Acceleration} = g - 0.8\,g = 0.2\,g = \frac{g}{5}.$$

Let W = weight of A
w = weight of B
F = net force available for acceleration = W — w
M = combined mass of both bodies = $\frac{W + w}{g}$
m = mass of B = $\frac{w}{g}$
a = acceleration
T = tension in cord.

$$\text{Then:}\quad a = \frac{F}{M} = (W - w) \div \frac{W + w}{g} = \frac{g\,(W - w)}{W + w}$$

$$T = w + m\,a = w + \frac{w}{g}a = w + \frac{w}{g} \cdot \frac{g\,(W - w)}{W + w} = w\left(1 + \frac{W - w}{W + w}\right).$$

(**c**) An "**Atwood's Machine**" consists essentially of a pulley, a flexible cord passing over the pulley, two equal weights (one suspended at each end of the cord), and a third weight, generally much lighter than either of the other two. The two equal weights balance each other by means of the pulley and cord. The third weight is laid upon one of the other two weights. The force of gravity, acting upon the third weight, then sets the masses of the three weights in motion at a small but constantly increasing velocity. In order to do this it must also overcome the friction of the pulley and cord, and the rigidity

of the latter; but, as these are made as slight as possible, they are, for convenience, neglected. The machine is used for illustrating the acceleration given to inert matter by unbalanced force, and forms an excellent example of the two distinct duties which a moving force generally has to perform, viz: (1st) the balancing of resistance, and (2nd) acceleration.

(d) In the case of **a locomotive, drawing a train on a level**, friction and the resistance of the air are the only resistances to be balanced; for the weight of the train here opposes no resistance. Unless the force of the steam is *more* than sufficient to balance the resistances, it cannot move the train. If it exceeds the resistances, the excess, however slight, gives motion to the inert matter of the train. If, at any moment while the train is moving, the force of the steam becomes *just equal to the resistances* (whether by an increase of the latter or by diminishing the force) the train will move on at a *uniform* velocity equal to that which it had at the moment when the force and resistance were equalized; and, if these could always be kept equal, it would so move on forever.

But so long as the excess of steam pressure over the resistances continues to act, the velocity is increased at each instant; for during each such instant the excess of force gives a small velocity *in addition* to that already existing.

On a level railroad, let

P = the total tractive force of the locomotive = say 13 tons
W = weight of locomotive = 50 tons
w = weight of train = 336 tons
R = resistance of locomotive (including internal friction, etc.) = 3 tons
r = resistance of train = 1 ton
F = net force available for acceleration = P — R — r = 9 tons

$$M = \text{mass of engine and train} = \frac{W + w}{g} = \frac{50 + 336}{32.2} = 12$$

$$m = \text{mass of train} = \frac{w}{g} = \frac{336}{32.2} = 10.44$$

a = acceleration
T = tension on draw-bar.

(Here the unit of mass is 2240 matts. See Art. 11 d, e.)

$$\text{Then: Acceleration} = a = \frac{F}{M} = \frac{9}{12} = 0.75 \text{ ft per second per second.}$$

The tension T on the draw-bar = resistance of train + force causing acceleration a, or $T = r + m\,a = 1 + 10.44 \times 0.75 = 1 + 7.83 = 8.83$ tons.

This tension, T, pulling backward against the locomotive, causes there a *retardation*, or *negative* acceleration, of $\frac{T}{\text{mass of locomotive}} = \frac{8.83\,g}{50} = 5.69$ ft per sec per sec, and thus reduces, by that amount, the acceleration which the locomotive would otherwise have, and which would be $= \frac{(P - R)\,g}{50} = \frac{10 \times 32.2}{50} = 6.44$. This, less 5.69, = 0.75 ft per sec per sec = acceleration of train.

(e) If the tractive force of a locomotive exceeds the resistances, due to friction, grades, and air, the velocity will be accelerated; but it then becomes more difficult to maintain the excess of force, for the pistons must travel faster through the cylinders, and the boiler can no longer supply steam fast enough to maintain the original cylinder pressure. Besides, some of the resistances increase with increase of velocity. We thus reach a speed at which the engine, although exerting its utmost force, can do no more than balance the resistances. The train then moves with a uniform velocity equal to that which it had when this condition was reached.

When it becomes necessary to stop at a station some distance ahead, steam is shut off, so that the steam force of the engine shall no longer counterbalance or destroy the resisting forces; and the number of the resistances themselves is increased by adding to them the friction of the brakes. The resistances, thus increased, are now the only forces acting upon the train, and their acceleration is *negative*, or a *retardation*. Hence, the train moves more and more slowly, and must eventually stop.

(f) **Caution.** When two opposite forces are in equilibrium, an addition to one of the forces does not always form an unbalanced force; for in many cases the *other force increases equally*, up to a certain point. For instance, when we attempt to lift a weight, W, its downward *resistance*, R, remains constantly just equal to our upward pull, P, however P may vary, until P *exceeds* W. Thus, R can never *exceed* W, but may be much less than it. Indeed, when we stop pulling, R ceases, although W (the attraction between the earth and the weight) of

course remains unchanged throughout. Such variation of resisting force, to meet varying demands, occurs in all those innumerable cases where structures sustain varying loads within their ultimate strength.

Art. 17 (a). Work. Force, when it moves a body,* is said to do "work" upon it. The *whole* work done by the force in moving the body through any distance is measured by multiplying the *force* by the distance; or, Work = Force × distance. If the *force* is taken in *pounds*, and the *distance* in *feet*, the product (or the *work* done) will be in *foot-pounds;* if the force is in tons and the distance in inches, the product will be in inch-tons; and so on.†

Thus, if a force of	moves a body through	we have work =
1 pound	10,000 feet	10,000 foot-pounds
100 pounds	100 "	10,000 "
10,000 "	1 foot	10,000 "

or, in any case, if a force of f pounds move a body through s feet, it does $f\,s$ foot-pounds of work. Thus **force is the linear rate of work.** ($f = f\,s \div s$.)

(b) With English measures, **the ordinary unit of work** is the **foot-pound. The metric unit of work** is the **kilogram-meter.** See Conversion Tables, p. 237.

In the C. G. S. system (Art. 11 *f*), 1 dyne, acting through 1 centimeter, does **1 erg (1 dyne-centimeter)** of work. 1 joule (p. 237) = 10,000,000 ergs = 0.7373 foot-pound. 1 foot-pound = about 13,563,000 ergs.

(c) In most cases, a portion at least of the **work** done by a force is **expended in overcoming resistances.** Thus, when a locomotive begins to move a train, a portion of its force works against, and balances, the resistances of friction or of an up-grade, while the remainder, acting as unbalanced force upon the inert mass of the train, increases its velocity.

An upward pull of exactly one pound will not raise a one pound weight, but will merely balance the downward force of gravity. If we increase the upward pull from one pound (= 16 ounces) to 17 ounces, the ounce so added, being unbalanced force, will give motion to the mass, and will accelerate its upward velocity as long as it continues to act. If we now reduce the upward pull to 1 pound, thus making it just equal to the downward pull of gravity, the body will move on upward with a uniform velocity; but if we reduce the upward force to 15 ounces (= $\frac{15}{16}$ pound), then there will be an unbalanced *downward* force of 1 ounce acting upon the body, and this downward force will generate in the body a downward or negative acceleration or *retardation*, and will *destroy* the upward velocity in the same time as the *upward* excess of 1 ounce required to *produce* it.

During any time, while the 17 ounces upward "force" were acting against the 16 ounces downward "resistance," the product of *total* upward force × distance must be *greater* than that of *resistance* × distance. The excess is the work done in accelerating the velocity, by virtue of which the body has acquired kinetic energy or capacity for doing work in coming to rest.

On the other hand, while the upward velocity was being *retarded*, the product of total upward force × dist was *less* than that of *resistance* × dist, the difference being the work done by the kinetic energy against the resistance of gravity.

In practice, the term "work" is usually restricted to that *portion* of the work which a force performs in balancing the *resistances* which act against it; in other words, to the work done by so much of the force as is equal to the resistance.

With this restriction, we have work = *force* × dist, = *resistance* × dist.

Thus, if the resistance be a friction of 4 lbs., overcome at every point along a distance of 3 feet; or if it be a weight of 4 lbs., lifted 3 feet high, then the work done amounts to 4 × 3 = 12 foot-lbs, provided the initial and the final velocities are equal.

(d) In cases **where the velocity is uniform,** as in a steadily running machine, the force is necessarily equal to the resistance; and where the velocities at the beginning and end of any work are equal (as where the machine starts from rest and comes to rest again) the *mean* force is equal to the *mean* resistance. In such cases, therefore, the two products, mean force × distance, and mean resistance × distance, are equal, and we have, as before,

Work = *force* × dist = *resistance* × dist.

---

* A man who is standing still is not considered to be working, any more than is a post or a rope when sustaining a heavy load; although he may be supporting an oppressive burden, or holding a car-brake with all his strength; for his force *moves nothing* in either case.

† These products must not be confounded with *moments*, = force × leverage.

(**f**) In calculating the work done by machinery, etc., allowance must be made for his expenditure of a portion of the work in overcoming resistances. Thus, in pumping water, part of the applied force is required to balance the friction of the different parts of the pump; so that a steam or water "power," exerting a force of 100 lbs., and moving 6 feet per second, cannot raise 100 lbs. of water to a height of 6 feet per second. Therefore machines, so far from *gaining power*, according to the popular idea, actually lose it in one sense of the word. In *starting* a piece of machinery, the forces employed have (1st) to balance, react against, or destroy the resisting force of friction and the cohesive forces of the material which is to be operated on; and (2d) to give motion to the unresisting matter of the machine and of the material operated on, after the resisting forces which had acted upon them have thus been rendered ineffective. But after the desired velocity has been established, the forces have *merely to balance the resistances* in order that the velocity may continue uniform.

(**g**) That portion of the work of a machine, etc., which is expended against friction is sometimes called "**lost work**" or "**prejudicial work,**" while only that portion is called "**useful work**" which renders visible and tangible service in the shape of output, etc. Thus, in pumping water, the work done in overcoming the friction of the pump and of the water is said to be lost or prejudicial, while the useful work would be represented by the product, weight of water delivered × height to which it is lifted.

The distinction, although artificial, and somewhat arbitrary, is often a very convenient one; but the work is of course not actually "lost," and still less is it "prejudicial;" for the water could not be delivered without first overcoming the resistances. A merchant might as well call that portion of his money lost which he expends for clerk-hire, etc.

(**h**) For a given force and *distance*, **the work done is independent of the time;** for the product, force × distance, then remains the same, whatever the time may be. But the distance through which a given *force* will work at a given velocity is of course proportional to the time during which it is allowed to work. Thus, in order to lift 50 pounds 100 feet, a man must do the same work, (= 5000 foot-pounds) whether he do it in one hour or in ten; but, if he exerts constantly *the same force*, he will lift 50 lbs. ten times as high in ten hours as in one, and thus will do ten times the work. Thus, for a given *force*, **the work is proportional to the time.**

Art. 18 (a), Power. The quantity of any work may evidently be considered without regard to the *time* required to perform it; but we often require to know the *rate* at which work can be done; that is, how much can be done within a certain *time*.

The rate at which a machine, etc. can work is called its *power*. Thus, in selecting a steam-engine, it is important to know how much it can do *per minute, hour, or day*. We therefore stipulate that it shall be of so many *horse-powers*; which means nothing more than that it shall be capable of overcoming resisting forces at the rate of so many times 33,000 foot-pounds per minute when running at a uniform velocity, *i. e.*, when force × distance = resistance × distance.

(**b**) The **horse-power**, 33,000 foot-pounds per minute, or 550 foot pounds per second, is the **unit of power, or of rate of work,** commonly used in connection with engines. The **metric horse-power**, called "force de cheval," "cheval-vapeur," or (German) "Pferdekraft," is 75 kilogram-meters per second = 542.48 ft.-lbs per sec. = 32,549 ft.-lbs. per minute = 0.9863 horse-power. 1 horse-power = 1.0138 "force de cheval." In theoretical Mechanics the **foot-pound per second** is used in English measure; and the **kilogram-meter per second** in metric measure,

1 foot-pound per second = 0.13825 kilogram-meter per second.
1 kilogram-meter per second = 7.2331 foot-pounds per second.

(**c**) Up to the time when the velocity becomes uniform, the **power**, or **rate of work,** of the train, in Art 16 (*d*), is *variable*, being gradually *accelerated*. For in each second it overcomes its resistances (and moves its point of application) *through a greater distance* than during the preceding second. Also, after the steam is shut off, the rate of work is variable, being gradually *retarded*. When the force of the steam just balances the resistances, the rate of work is uniform.

(**d**) **Power = force × velocity.** Since the *rate* of work is equal to the work done *in a given time*, as so many *foot-pounds per second*, we may find it by dividing the work in foot-pounds done during any given time by the number of seconds in that time. Thus

$$\text{Power} = \text{rate of work} = \frac{\text{force in pounds} \times \text{distance in feet}}{\text{time in seconds}}$$

But this is equivalent to

$$\text{Power} = \text{rate of work} = \text{force in pounds} \times \frac{\text{distance in feet}}{\text{time in seconds}}$$

$$= \text{force in pounds} \times \text{velocity in feet per second.}$$

Or, if we treat only of the work of *that force which overcomes resistances:* or in cases where the velocity is either uniform throughout or the same at the beginning and end of the work;

$$\begin{array}{c}\text{Power,} \\ \text{in ft-lbs. per sec.}\end{array} = \begin{array}{c}\text{rate of work} \\ \text{in ft-lbs. per sec.}\end{array} = \begin{array}{c}\text{resistance,} \\ \text{in lbs.}\end{array} \times \begin{array}{c}\text{velocity,} \\ \text{in ft per sec.}\end{array}$$

Thus, if the resistance is 3300 lbs. and is overcome through a distance of 10 feet in every minute; or if the resistance is 33 lbs. and is overcome through a distance of 1000 feet per minute, the rate of the work is in each case the same, namely, 33,000 foot-pounds per minute, or one horse-power; for

$$\overset{\text{lbs.}}{3300} \times \overset{\text{vel.}}{10} = \overset{\text{lbs.}}{33} \times \overset{\text{vel.}}{1000} = 33{,}000 \text{ foot-pounds per minute.}$$

(c) The same "power" which will overcome a given resistance through a given distance, in a given time, will also overcome any other resistance through any other distance, in that same time, provided the resistance and distance when multiplied together give the same amount as in the first case. Thus, the power that will lift 50 pounds through 10 feet in a second, will in a second lift 500 pounds, 1 foot; or 25 pounds, 20 feet; or 5000 pounds $\frac{1}{10}$ of a foot. In practice, the adjustment of the speed to suit different resistances, is usually effected by the medium of **cog-wheels, belts, or levers.** By means of these the engine, water-wheel, horse, or other motive power, exerting a given force and running at a given velocity, may be made to overcome small resistances rapidly, or great ones slowly, as desired.

Art. 19 (a). The work which a body can do by virtue of its motion; or (which is the same thing) **the work required to bring the body to rest. Kinetic energy, vis viva, or "living force."** As already remarked, a force equal to the weight of any body, at any place, will, in one second, give to the mass or matter of the body a velocity $= g$, or (on the earth's surface) about 32.2 feet per second. Or if a body be thrown upward with a velocity $= g$, its weight will stop it in one second.

Since, in the latter case, the velocity at the beginning and at the end of the second are, respectively, $= g$ feet per second, and $= 0$, the *mean* velocity of the body is $\frac{g}{2}$ feet per second. Therefore, during the second it will rise $\frac{g}{2}$ feet, or about 16 feet. In other words, the work which any body can do, by virtue of being thrown vertically upward with an initial velocity (velocity at the *start*) of g feet per second, is equal to the product of its weight multiplied by $\frac{g}{2}$ feet. Or,

$$\text{work in foot-pounds} = \text{weight} \times \frac{g}{2}$$

Notice that in this case (since the initial velocity v is equal to g), $\frac{v}{g} = 1$.

Suppose now that the same body be thrown upward with *double* the former velocity; *i. e.*, with an initial velocity equal to $2\,g$ (or about 64 feet per second). Since gravity requires (Art. 8 *c*), *two* seconds to impart or destroy this velocity, the body will now move upward during *two* seconds, or twice as long a *time* as before. But its mean *velocity* now is g, or twice as great as before. Therefore, moving for double the time and with double the velocity, it will travel *four times* as *far*, overcoming the same resistance as before (viz.: its own weight) through *four* times the distance.

Thus, by making its initial velocity $v = 2\,g$, *i. e.*, by *doubling* its $\frac{v}{g}$, making it $= 2$, we have enabled the body to do *four* times the work which it could do when its $\frac{v}{g}$ was 1; so that the work in the second case is equal to the

product of that in the first case multiplied by the *square* of $\frac{v}{g}$; or,

$$\text{Work in ft-lbs.} = \text{weight} \times \frac{g}{2} \times \left(\frac{v}{g}\right)^2$$
$$= \text{weight} \times \frac{g}{2} \times \frac{v^2}{g^2}$$
$$= \text{weight} \times \frac{v^2}{2g}$$

And it is plain that this would be the case for any *other* velocity. Now the total amount of the work which the body can do, is independent of the amount of the resistance against which it is done; for if we increase the resistance we diminish the distance in the same proportion, so that their product, or the amount of work, remains the same. The above formula, therefore, applies to all cases; *i. e.*, the **total amount of work,** in foot pounds, which any body will do, against any resistance, by virtue of its motion alone, in coming to rest, is

$$\textbf{Work} = \text{weight of moving body, in lbs.} \times \frac{\text{square of its velocity in ft per sec'd}}{2g}$$
$$= \text{weight of moving body, in lbs.} \times \text{fall in ft required to give the velocity}$$
$$= \frac{\text{weight of moving body, in lbs.}}{g} \times \frac{\text{square of its velocity in ft per second}}{2}$$

In these equations, the *weight* is that which the body has in any given place, and g is the acceleration of gravity at that same place.

(b) Since the $\frac{\text{weight of a body}}{g}$ is its mass (Art. 11, p. 336), the last formula becomes, by "method A," Art. 11 (*d*),

$$\frac{\textbf{work}}{\text{in foot-}\textit{pounds}} = \text{mass of moving body in ``}\textit{matts}\text{''} \times \frac{\text{square of its velocity in ft per second}}{2}$$

and by "method B," Art. 11 (*e*),

$$\frac{\textbf{work}}{\text{in foot-}\textit{poundals}} = \text{mass of moving body in }\textit{pounds} \times \frac{\text{square of its velocity in ft per second}}{2}$$

(c) In the above equations the *left* hand side represents the *work* (or resistance overcome through a distance) in any given case, while the *right* hand side represents the **kinetic energy** of the body, by which it is enabled to do that work. Some writers call this energy **"vis viva,"** or "living force" a name formerly given (for convenience) to a quantity just *double* the energy, or = mass × velocity^2.

(d) As an illustration of the foregoing, take a train weighing 1,120,000 pounds, and moving at the rate of 22 feet per second. The kinetic energy of such a train is

$$\text{energy} = \text{weight} \times \frac{\text{velocity}^2}{2g}; \quad \text{or,}$$

$$1{,}120{,}000 \text{ lbs.} \times \frac{22^2}{64.4} = 8{,}400{,}000 \text{ ft.-lbs.}$$

That is, if steam be shut off, the train will perform a work of 8,400,000 ft.-lbs. in coming to rest. Thus, if the sum of all the resistances (of friction, air, grades, curves, etc.) remained constantly = 5000 lbs.,* the train would travel

$$\frac{8{,}400{,}000 \text{ ft.-lbs.}}{5000 \text{ lbs.}} = 1680 \text{ ft.}$$

(e) We thus see that the total quantity of work which a body can do by virtue of its motion alone, and without assistance from extraneous forces, is in proportion to the weight of the body and to the *square* of its velocity when it begins to do the work. For example, suppose that a train, at the moment when steam is shut off, has a velocity of 10 miles an hour and that the kinetic energy, which that velocity gives it, will by itself carry the train against the

* In practice, this would not be the case.

resistances of the road, etc., for a distance of *one* quarter of a mile before it stops. Then, if steam be shut off while the train is moving at 5, 20, 30 or 40 miles per hour (*i. e.* with ½, 2, 3 or 4 times 10 miles per hour) the train will travel 1/16, 1, 2¼ or 4 miles (or ¼, 4, 9 or 16 times ¼ mile) before coming to rest. The resistances are here supposed to be uniform.

But the *time rate* of work done is proportional simply to the resistance and the *velocity* (Art. 18 *d*). Therefore, the locomotive whose steam is shut off at 20, 30 or 40 miles per hour, will require, for running its 4, 9 or 16 quarters of a mile, but 2, 3 or 4 times as many seconds as it required at 10 miles per hour.

The same principle applies to all cases of acceleration or of retardation.

For instance, in the case of a falling body, the *distance* through which it must fall, in order to acquire any given velocity, is as the *square* of that velocity, but the *time* required is simply as the *velocity*. Also, if a body is thrown vertically upward with any given velocity, the *height* to which it will rise, by the time gravity destroys that velocity, will be as the *square* of the velocity, but the *time* will be simply as the velocity.

Art. 20 (a). When a body, starting from rest, and moving, under the action of a constant force, during a time, t, has acquired a velocity, v, its *mean* velocity, during the time, t, is ½ v; and the distance traversed is $s = \frac{1}{2} v\, t$. Since $m\, v = f\, t$ (Art. 12) we have:

$$\frac{m\ v^2}{2} = m\ v \cdot \frac{v}{2} = f\ t \cdot \frac{v}{2} = f\ s;$$

or, **the kinetic energy**, $K = \frac{1}{2} m\, v^2$, of a moving body, **is equal to the work, f s, done** by a force, f, in producing or destroying the momentum, m v, while traversing the space, s.

$$\text{Since } f\ s = K = \frac{m\ v^2}{2},$$

we have

$$\frac{f\ s}{t} = \frac{K}{t} = \frac{m\ v^2}{2\ t} = \frac{m\ v}{2} \cdot \frac{v}{t} = \frac{m\ v}{2} \cdot a = \frac{m\ v}{2} \cdot \frac{f}{m};$$

or: **time rate of work**

= mean momentum $\times$ acceleration
= mean momentum $\times$ force intensity;

or

$$\frac{\text{ft-lbs}}{\text{sec}} \cdot \frac{\text{poundals}}{\text{lb}} = \frac{\text{ft-poundals}}{\text{second}}.$$

In other words, if a mass, of m lbs, be moving with velocity, v ft per sec, it has a momentum of m v ft-lbs per second and an energy, K, of $\frac{m\ v^2}{2}$ ft-lbs; and $\frac{m\ v^2}{2}$ ft-lbs, = f s ft-poundals, of work must have been done upon it, in order to give it the velocity, v; and an equal amount of work must be done in order to bring it to rest.

Thus, if m = 4 lbs, and v = initial velocity = 12 ft per sec; we have $m\ v = 4 \times 12 = 48$ ft-lbs per sec, and $K = f\ s = \frac{m\ v^2}{2} = m\ v \cdot \frac{v}{2} = 48 \times 6 = 288$ ft-lbs.

By selecting different forces, f, to bring this mass to rest, we obtain different accelerations, different time rates of work, etc.

The momentum, m v, at any moment, is necessarily double the *mean* momentum, $\frac{m\ v}{2}$, which the mass has during the time, $t = \frac{v}{a}$, in which it acquires or loses the velocity, v, under the action of any constant force, f.

Let the weight of a falling body = W, and the acceleration of gravity = g. Then $W \cdot \frac{v}{2} \cdot \frac{v}{g}$ = weight $\times$ mean velocity $\times$ time of fall = weight $\times$ distance fallen = $W \cdot \frac{v^2}{2\ g}$ = the work done = $\frac{W}{g} \cdot \frac{v^2}{2} = \frac{m\ v^2}{2}$ = the kinetic energy acquired.

Art. 21 (a). Energy is indestructible. Energy, expended in work, is not destroyed. It is either transferred to other bodies, or else stored up in the body itself; or part may be thus transferred, and the rest thus stored. But, although energy cannot be destroyed, it may be rendered useless to us. Thus, a moving train, in coming to rest on a level track, transfers its kinetic energy into other kinetic energy; namely, the useless heat due to friction at the rails, brakes and journals; and this heat, although none of it is *destroyed*, is dissipated in the earth and air so as to be practically beyond our recovery.

Art. 22 (a). Potential energy, or possible energy, may be defined as stored-up energy. We lift a one-pound body one foot by expending upon it one foot-pound of energy. But this foot-pound is stored up in the "system" (composed of the earth and the body) as an addition to its stock of potential energy. For, while the stone falls through one foot,* the system will acquire a kinetic energy of one foot-pound, and will part with one foot-pound of its potential energy.

(**b**) The *potential* energy of a "system" of bodies (such as the earth and a weight raised above it, or the atoms of a mass of powder, or those of a bent spring) depends upon the relative *positions* of those bodies, and upon their *tendencies to change* those positions. The *kinetic* energy of a system (such as the earth and a moving train of cars) depends upon the *masses* of its bodies and upon their *motion* relatively to each other.

Familiar instances of potential energy are—the weight or spring of a clock when fully or partly wound up, and whether moving or not; the pent-up water in a reservoir; the steam pressure in a boiler; and the explosive energy of powder. We have mechanical energy in the case of the weight or springs or water; heat energy in the case of the steam; and chemical energy in that of the powder.

(**c**) In many cases we may conveniently estimate the *total* potential energy of a system. Thus (neglecting the resistance of the air) the explosive energy of a pound of powder is = the weight of any given cannon ball × the height to which the force of that powder could throw it, = the weight of the ball × (the square of the initial velocity given to it by the explosion) ÷ $2g$. But in other cases we care to find only a certain definite *portion* of the total potential energy. Thus, the *total* potential energy of a clock-weight* would not be exhausted until the weight reached the center of the earth; but we generally deal only with that portion which was stored in it by winding-up, and which it will give out again as kinetic energy in running down. This portion is = the weight × the height which it has to run down = the weight × (the square of the velocity which it would acquire in falling *freely* through that height) ÷ $2g$.

(**d**) There are many cases of energy in which we may hesitate as to whether the term "kinetic" or "potential" is the more appropriate. Thus, the pressure of steam in a boiler is believed to be due to the violent *motion* of the particles of steam, which bombard the inner surface of the boiler-shell; so that, from *this* point of view, we should call the energy of steam *kinetic*. But, on the other hand, the shell itself remains stationary; and, until the steam is permitted to escape from the boiler, there is no outward evidence of energy in the shape of work. The energy remains stored up in the boiler ready for use. From *this* point of view, we may call the energy of steam *potential* energy.

(**e**) It seems reasonable to suppose that further knowledge, as to the nature of other forms of energy, apparently potential (as is that of steam), might reveal the fact that all energy is ultimately kinetic.

Art. 23 (a). There is much **confusion of ideas** in regard to those actions to which, in Mechanics, we give the names, "**force**," "**energy**," "**power**," etc. This arises from the fact that, in every-day language, these terms are used indiscriminately to express the same ideas.

Thus, we commonly speak of the "force" of a cannon-ball flying through the air, meaning, however, the repulsive force which *would be* exerted between the ball and a building, etc. with which it might come into contact. This force would tend to move a part of the building along in the direction of the flight of the ball, and would move the ball backward; (*i. e.*, would retard its forward motion). But this great repulsive "*force*" does not exist until the ball strikes the building. Indeed, we cannot even tell, from the velocity and weight of the ball, what the *amount* of the force will be, for this depends upon the strength, etc., of the *building*. If the building is of glass, the force may be so slight as scarcely to retard the motion of the ball perceptibly, while, if the building is an

*For convenience we may thus speak of the energy of a *system* of bodies (the earth and the clock-weight) as residing in only *one* of the bodies.

earth embankment, the force will be much greater, and may retard the motion of the ball so rapidly as to entirely stop it before it has gone a foot farther.

The moving ball has great (kinetic) *energy;* but the only *force* that it exerts during its flight is the comparatively very slight one required to push aside the particles of air.

The energy of the ball, and therefore the total work which it can do, are independent of the nature of the obstruction which it meets; but since the work is the product of the resistance offered and the distance through which it can be overcome, the distance must be inversely as the resistance offered; or (which is the same thing) inversely as the force required of, and exerted by, the ball in balancing that resistance.

Since work, in ft.-lbs. = force, in lbs, $\times$ distance traversed, in feet, we have

$$\text{force, in lbs.} = \frac{\text{work, in ft.-lbs.}}{\text{distance traversed, in feet}} = \frac{\text{rate of work,}}{\text{in ft.-lbs. } per\ foot.}$$

Art. 24 (a). An impact, blow, stroke or collision takes place when a moving body encounters another body. The peculiarity of such cases is that the *time of action* of the repulsive force due to the collision is so *short* that generally it is impossible to measure it, and we therefore cannot calculate the force from the momentum produced by it in either of the two bodies: but since both bodies undergo a great change of velocity (*i. e.*, a great acceleration) during this short time, we know that the repulsive force acting between them must be very great.

We shall consider only cases of **direct impact**, or impact where the centers of gravity of the two bodies approach each other in one straight line, and where the nature of the surfaces of contact is such that the repulsive force caused by the impact also acts through those centers and in their line of approach

(**b**) This force, acting equally upon the two bodies (Art. 5 *f*), for the same length of time (namely, the time during which they are in contact), necessarily produces equal and opposite changes in their momentums (Art. 12, p 338). Hence, the total momentum (or product, mass $\times$ velocity) of the *two* bodies is always the same after impact as it was before

(**c**) But the relative behavior of the two bodies, after collision, depends upon their elasticity. If they could be perfectly inelastic, their velocities, after impact, would be equal. In other words, they would move on together. If they could be perfectly *elastic*, they would separate from each other, after collision, with the same velocity with which they approached each other before collision.

(**d**) Between these two extremes, neither of which is ever perfectly realized in practice, there are all possible degrees of elasticity, with corresponding differences in the behavior of the bodies The subject, especially that of *indirect* impact, is a very complex one, but seldom comes up in practical civil engineering.

(**e**) "In some careful experiments made at Portsmouth dock-yard, England, a man of medium strength, and striking with a maul weighing 18 lbs., the handle of which was 44 inches long, barely *started* a bolt about ⅛ of an inch at each blow; and it required a quiet pressure of 107 tons to press the bolt down the same quantity; but a small additional weight pressed it completely home."

GRAVITY, FALLING BODIES.

Bodies falling vertically. A body, falling freely in vacuo from a state of rest, acquires, by the end of the first second, a velocity of about 32.2 feet per second; and, in each succeeding second, an *addition* of velocity, or acceleration, of about 32.2 feet per second. In other words, the velocity receives in each second an acceleration of about 32.2 feet per second, or is accelerated at the *rate* of about 32.2 feet per second, *per second.* This rate is generally called (for brevity, see foot-note,† p. 334), simply the **acceleration of gravity** (but see * below), and is denoted by **g.** It increases from about 32.1 feet per second, per second, at the equator, to about 32.5 at the poles. In the latitude of London it is 32.19. These are its values at sea-level; but at a height of 5 miles above that level it is diminished by only about 1 part in 400. For most practical purposes it may be taken at 32.2.

Caution. Owing to the resistance of the air none of the following rules give perfectly accurate results in practice, especially at great vels. The greater the specific gravity of the body the better will be the result. The air resists both **rising** and **falling** bodies.

If a body be thrown vertically upwards with a given vel, it will rise to the same height from which it must have fallen in order to acquire said vel; and its vel will be retarded in each second 32.2 ft per sec. Its average ascending velocity will be half of that with which it started; as in all other cases of uniformly retarded vel. In falling it will acquire the same vel that it started up with, and in the same time. See above Caution.

Acceleration acquired*

in a given time $= g \times$ time

in a given fall from rest $= \sqrt{2\,g \times \text{fall}}$.

in a given fall from rest and given time $= \dfrac{\text{twice the fall}}{\text{time}}$

Time required

for a given acceleration $= \dfrac{\text{acceleration}}{g}$

for a given fall from rest $= \sqrt{\dfrac{\text{fall}}{\frac{1}{2}\,g}} = \dfrac{\text{fall}}{\frac{1}{2}\text{ final velocity}}$

for a given fall from rest or otherwise $= \dfrac{\text{fall}}{\text{mean vel}} = \dfrac{\text{fall}}{\frac{1}{2}(\text{initial vel} + \text{final vel})}$

Fall

in a given time (starting from rest) $=$ time $\times \frac{1}{2}$ final vel $=$ time$^2 \times \frac{1}{2} g$

in a given time (starting from rest or otherwise) $=$ time $\times$ mean vel $=$ time $\times \dfrac{\text{initial vel} + \text{final vel}}{2}$

reqd for a given acceleration (starting from rest) $= \dfrac{\text{acceleration}^2}{2\,g}$.

during any one given second (counting from rest)

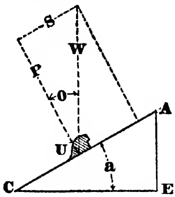
$$= g \times \left(\text{number of the second (1st, 2d, \&c)} - \tfrac{1}{2}\right)$$

during any equal consecutive times (starting from rest) $\propto$ 1, 3, 5, 7, 9, &c.

Calling $g = 32.2$ we have	At the end of the 1st.	2d.	3d.	4th.	5th.	6th.	7th.	8th.	9th.	10th seconds
Velocity; ft per sec.	32.2	64.4	96.6	128 8	161.0	193.2	225 4	257.6	289.8	322.0
Dist fallen since end of preceding sec; ft.	16.1	48.3	80.5	112.7	144.9	177.1	209.3	241.5	273.7	305.9
Total dist fallen; ft.	16.1	64.4	144 9	257.6	402.5	579.6	788 9	1030 4	1304 1	1610.0

* By "acceleration," *in this article*, we mean the *total* acceleration; *i. e.*, the whole change of velocity occurring in the given time or fall. For the *rate* of acceleration

Descent on inclined planes. When a body, U, is placed upon an inclined plane, A C, its whole weight W is not employed in giving it velocity (as in the case of bodies falling vertically) but a portion, P, of it (= W × cosine of o = W × cosine of a*) is expended in perpendicular pressure against the plane; while only S, (= W × sine of o = W × sine of a,*) acts upon U in a direction parallel to the surface A C of the plane, and tends to slide it down that surf



The acceleration, generated in a given body in a given time, is proportional to the force acting upon the body in the direction of the acceleration

Hence if we make W to represent by scale the acceleration g (say 32.2 ft per sec per sec) which grav would give to U in a sec if falling freely, then S will give, by the same scale, the acceleration in ft per sec which the actual sliding force S would give to U in one sec if there were no friction between U and the plane. We have therefore

theoretical acceleration down the plane = g × sine of a.

Therefore we have only to substitute "g sin a" in place of "g;" and the *sloping* distance or "slide" A C in place of the corresponding *vertical* distance or "fall" A E in the equations, in order to obtain the accelerations etc as follows:

on an inclined plane without friction.

Acceleration† of sliding velocity

$$\text{in a given time} = \left.\begin{matrix}\text{vert accel acquired in falling}\\ \text{vert during the same time}\end{matrix}\right\} \times \sin a$$

$$= g.\ \sin a \times \text{time}$$

$$\left.\begin{matrix}\text{in a given slide, as A C,}\\ \text{from rest}\end{matrix}\right\} = \frac{\text{slide}}{\tfrac{1}{2}\ \text{time}}$$

$$= \left\{\begin{matrix}\text{vert accel acquired in falling}\\ \text{freely thro the corresponding}\\ \text{vert ht A E}\end{matrix}\right\} = \sqrt{2\,g.\ \text{A E}}$$

$$= \sqrt{2\ g.\ \sin a \times \text{slide}}$$

Time required

$$\text{for a given sliding acceleration} = \frac{\text{sliding acceleration}}{g.\ \sin a}$$

$$\text{for a given slide, as A C, from rest} = \frac{\text{slide}}{\tfrac{1}{2}\ \text{final sliding velocity}} = \sqrt{\frac{\text{slide}}{\tfrac{1}{2}\,g.\ \sin a}}$$

$$= \frac{\text{time reqd to fall freely thro the corresponding vert ht A E}}{\sin a}$$

$$\left.\begin{matrix}\text{for a given slide, from}\\ \text{rest or otherwise}\end{matrix}\right\} = \frac{\text{slide}}{\text{mean sliding vel}} = \frac{\text{slide}}{\tfrac{1}{2}\,(\text{initial} + \text{final sliding vels})}$$

$$\textbf{Cosine a} = \frac{\text{base E C}}{\text{length A C}} = \frac{\text{horizontal stretch, as E C, of any length, as A C}}{\text{that length}} = \frac{\sqrt{\text{A C}^2 - \text{A E}^2}}{\text{A C}}$$

$$\textbf{Sine a} = \frac{\text{height A E}}{\text{length A C}} = \frac{\text{fall, A E, in any given length, A C}}{\text{that length}} = \frac{\sqrt{\text{A C}^2 - \text{E C}^2}}{\text{A C}}$$

* Because o and a are equal.

† By acceleration, *in this article*, we mean the total acceleration, *i. e.*, the whole change in velocity occurring in the given time or slide. For the *rate* of acceleration we use simply the letter g.

Slide, as A C

in a given time, starting from rest = time × ½ final sliding vel
= time² × ½ g. sin a.

in a given time, starting from rest or otherwise = time × mean sliding vel
= time × ½ (initial + final, sliding vels)

required for a given sliding acceleration (starting from rest) $= \dfrac{\text{sliding acceleration}^2}{2\, g.\ \sin a}$

But in practice the sliding on the plane is always opposed by friction. To include the effect of friction, we have only to substitute

"$g \times \left[\sin a - (\cos a.\ \text{coeff fric})\right]$" in place of "$g.\ \sin a$" in the above equations. Because

Friction = Perpendicular pressure P × coefficient of friction
= weight W × cosine a × coefficient of friction

and

retardation of friction = g × cosine a × coefficient of friction.

Resultant sliding acceleration

= theoretical sliding accel (due to the sliding force, S) — retardation of fric
= (g. sin a) — (g cosine a. coeff fric)
= $g \times \left[\sin a - (\text{cosine } a.\ \text{coeff fric})\right]$

If the retardation of friction (= g. cos a × coeff fric) is *not less* than the total or theoretical accel ("g sin a") the body cannot slide down the plane.

PENDULUMS.

THE numbers of vibrations which diff pendulums will make in any given place in a given time, are *inversely* as the square roots of their lengths; thus, if one of them is 4, 9, or 16 times as long as the other, its sq rt will be 2, 3, or 4 times as great; but its number of vibrations will be but ½, ⅓, or ¼ as great. The times in which diff pendulums will make a vibration, are *directly* as the sq rts of their lengths. Thus, if one be 4, 9, or 16 times as long as the other, its sq rt will be 2, 3, or 4 times as great; and so also will be the time occupied in one of its vibrations.

The length of a pendulum vibrating seconds at the level of the sea, in a vacuum, in the lat of London (51½° North) is 39.1393 ins; and in the lat of N. York (40¾° North) 39.1013 ins [illegible]uator about $\frac{1}{10}$ inch shorter; and at the poles, about $\frac{1}{10}$ inch longer. Approximately enough for experiments which occupy but a few sec, we may at any place call the length of a seconds pendulum in the open air, 39 ins; half sec, 9¾ ins; and may assume that long and short vibrations of the same pendulum are made in the same time; which they actually are, *very* nearly. For measuring depths, or dists by sound, a sufficiently good sec pendulum may be made of a pebble (a small piece of metal is better) and a piece of thread suspended from a common pin The length of 39 ins should be measured from the centre of the pebble

In starting the vibrations, the pebble, or *bob*, must not be *thrown* into motion, but merely *let drop*, after extending the string at the proper height.

To find the length of a pendulum reqd to make a given number of vibrations in a min, divide 375 by said reqd number. The square of the quot will be the length in ins, near enough for such temporary purposes as the foregoing. Thus, for a pendulum to make 100 vibrations per min, we have $\frac{375}{100} = 3.75$; and the square of $3.75 = 14.06$ ins, the reqd length.

To find the number of vibrations per min for a pendulum of given length, in ins, take the sq rt of said length, and div 375 by said sq rt. Thus, for a pendulum 14.06 ins long, the sq rt is 3.75; and $\frac{375}{3.75} = 100$, the reqd number.

REM 1. By practising before the sec pendulum of a clock, or one prepared as just stated, a person will soon learn to count 5 in a sec, for a few sec in succession; and will thus be able to divide a sec into 5 equal parts; and this may at times be useful for very rough estimating when he has no pendulum.

Centre of Oscillation and Percussion.

REM. 2. When a pendulum, or any other suspended body, is vibrating or oscillating backward and forward, it is plain that those particles of it which are far from the point of suspension move faster than those which are near it But there is always a certain point in the body, such that if *all* the particles were concentrated at it, so that all should move with the same actual vel, neither the number of oscillations, nor their angular vel, would be changed. This point is called the *center of oscillation*. It is not the same as the cen of grav, and is always farther than it from the point of suspension. It is also the *centre of percussion* of the suspended vibrating body. The dist of this point from the point of susp is found thus: Suppose the body to be divided into many (the more the better) small parts; the smaller the better. Find the weight of each part. Also find the cen of grav of each part; also the dist from each such cen of grav to the point of susp. Square each of these dists, and mult each square by the wt of the corresponding small part of the body. Add the products together, and call their sum *p*. Next mult the weight of the entire body by the dist of its cen of grav from the point of susp. Call the prod *g*. Divide *p* by *g*. This *p* is the **moment of inertia** of the body, and if divided by the wt of the body the sq rt of the quotient will be the **Radius of Gyration.**

Angular Velocity.

When a body revolves around any axis, the parts which are farther from that axis move faster than those nearer to it. Therefore we cannot assign a stated linear velocity in feet per second, or miles per hour etc, that shall apply to *every part* of it. But every part of the body revolves around an entire circle, or through an angle of 360°, in the same time. Hence, all the parts have the same velocity in *degrees* per second, or in *revolutions* per second. This is called the angular velocity. Scientific writers measure it by the length of the arc described by any point in the body in a given time, as a second, the length of the arc being measured by the number of times the length *of its own radius* is contained in it. When so measured,

$$\begin{array}{c}\text{Angular velocity}\\ \text{in radii per second}\end{array} = \frac{\text{linear velocity (in feet etc) per sec}}{\text{length of radius (in feet etc)}}$$

Here, as before, the angular velocity is the same for all the points in the body, because the velocities of the several points are directly as their radii or distances from the axis of revolution.

In each revolution, each point describes the circumference of the circle in which it revolves $= 2\pi r$ ($\pi = 3.1416$ etc; r = radius of said circle). Consequently, if the body makes n revolutions per second, the length of the arc described by each point in one second is $2\pi r n$; and the angular velocity of the body, or *linear* velocity of any point *measured in its own radii*, is

$$a = \frac{2\pi r n}{r} = 2\pi n = \text{say } 6.2832 \times \text{revs per } \textit{second} = \text{say } .1047 \times \text{revs per } \textit{minute}.$$

Moment of Inertia.

Suppose a body revolving around an axis, as a grindstone; or oscillating, like a pendulum. Suppose that the distance from the axis of revolution (which, in the pendulum, is the point of suspension) to each individual particle of the body, has been measured; and that the square of each such distance has been multiplied by the weight of that particle to which said distance was measured.

Slide, as A C

in a given time, starting from rest $= \text{time} \times \frac{1}{2}$ final sliding vel

$= \text{time}^2 \times \frac{1}{2} g. \sin a.$

in a given time, starting from rest or otherwise $=$ time $\times$ mean sliding vel

$= \text{time} \times \frac{1}{2}$ (initial + final, sliding vels)

required for a given sliding acceleration (starting from rest) $= \dfrac{\text{sliding acceleration}^2}{2\, g. \sin a}$

But in practice the sliding on the plane is always opposed by friction. To include the effect of friction, we have only to substitute

"$g \times \left[\sin a - (\cos a.\ \text{coeff fric})\right]$" in place of "$g. \sin a$" in the above equations. Because

Friction = Perpendicular pressure P $\times$ coefficient of friction

= weight W $\times$ cosine a $\times$ coefficient of friction

and

retardation of friction = g $\times$ cosine a $\times$ coefficient of friction.

Resultant sliding acceleration

= theoretical sliding accel (due to the sliding force, S) — retardation of fric

$= (g. \sin a) - (g\ \text{cosine}\ a.\ \text{coeff fric})$

$= g \times \left[\sin a - (\text{cosine}\ a.\ \text{coeff fric})\right]$

If the retardation of friction ($= g. \cos a \times$ coeft fric) is *not less* than the total or theoretical accel ("$g \sin a$") the body cannot slide down the plane.

PENDULUMS.

The numbers of vibrations which diff pendulums will make in any given place in a given time, are *inversely* as the square roots of their lengths; thus, if one of them is 4, 9, or 16 times as long as the other, its sq rt will be 2, 3, or 4 times as great; but its number of vibrations will be but ½, ⅓, or ¼ as great. The times in which diff pendulums will make a vibration, are *directly* as the sq rts of their lengths. Thus, if one be 4, 9, or 16 times as long as the other, its sq rt will be 2, 3, or 4 times as great; and so also will be the time occupied in one of its vibrations.

The length of a pendulum vibrating seconds at the level of the sea, in a vacuum, in the lat of London (51½° North) is 39.1393 ins; and in the lat of N. York (40¾° North) 39.1013 ins quator about $\frac{1}{10}$ inch shorter; and at the poles, about $\frac{1}{10}$ inch longer. Approximately enough for experiments which occupy but a few sec, we may at any place call the length of a seconds pendulum in the open air, 39 ins; half sec, 9¾ ins; and may assume that long and short vibrations of the same pendulum are made in the same time; which they actually are, *very* nearly. For measuring depths, or dists by sound, a sufficiently good sec pendulum may be made of a pebble (a small piece of metal is better) and a piece of thread suspended from a common pin The length of 39 ins should be measured from the centre of the pebble

Table of Radii of Gyration.—CONTINUED.

Body	Revolving around	Radius of Gyration
Hollow sphere of any thickness	a diameter	$\sqrt{\frac{2\,(\text{outer rad}^5 - \text{inner rad}^5)}{5\,(\text{outer rad}^3 - \text{inner rad}^3)}}$
ditto, thin	ditto	approx (outer rad + inner rad) $\times$ .4085
ditto, infinitely thin (spherical surface)	ditto	radius of sphere $\times \sqrt{\frac{2}{3}}$ = radius of sphere $\times$ about .8165
Straight line, *a b*	any point, *x*, in its length	$\sqrt{\frac{a\,x^3 + x\,b^3}{3\,a\,b}}$
a *x* *c* *b*	either end, *a* or *b*	length *a b* $\times \sqrt{\frac{1}{3}}$ = length *a b* $\times$ about .5775
	its center, *c*	*a c* $\times \sqrt{\frac{1}{3}}$ = length *a b* $\times$ about .2887
Solid cone	its axis	radius of base of cone $\times \sqrt{.3}$ = radius of base of cone $\times$ .5477
Circular plate, of rectangular cross section	See Solid cylinder	For the *thickness* of plate or ring, measured perpendicularly to the plane of the circumference, take the *length* of the cylinder.
Circular ring, of rectangular cross section	See Hollow cylinder	
Square, rectangle and other surfaces	For *least* radius of gyration, or that around the *longest* axis, see pp 353 *a* and *b*.	

Relations of least radius of gyration, r, and least side, D.

In any cross section, let

I = least moment of inertia;
a = area;
r = $\sqrt{I/a}$ = least rad of gyration;
D = least external diam or side;
d = least internal diam or side;

B = greatest external diam or side;
b = greatest internal diam or side;
t = thickness of wall;
c = D/t; $1/12$ = 0 0833
m = B/D; $\sqrt{12}$ = 3.4641

We then have the following relations:

Cross Section	r	r^2	$\frac{D}{r}$	$\left(\frac{D}{r}\right)^2$
 Solid square	$\frac{D}{\sqrt{12}}$	$\frac{D^2}{12}$	$\sqrt{12}$	12
 Hollow square, of uniform thickness *	$\sqrt{\frac{D^2+d^2}{12}}$	$\frac{D^2+d^2}{12}$	$\sqrt{\frac{12\ D^2}{D^2+d^2}}$ *	$\frac{12\ D^2}{D^2+d^2}$ *
 Solid rectangle,	$\frac{D}{\sqrt{12}}$	$\frac{D^2}{12}$	$\sqrt{12}$	12
 Hollow rectangle, of uniform thickness †	$\sqrt{\frac{D^3B-d^3b}{12(DB-db)}}$	$\frac{D^3B-d^3b}{12(DB-db)}$	$\sqrt{12D^2\frac{DB-db}{D^3B-d^3b}}$ †	$12D^2\ \frac{DB-db}{D^3B-d^3b}$

CENTRIFUGAL FORCE.

When a body *a*, Fig. 1, moves in a circular path *abd*, it tends, at each point, as *a* or *b*, to move in a tangent *at* or *bt'* to the circle at that point. But at each point, as *a*, etc., in the path, it is *deflected* from the tangent by a force acting toward the center, *c*, of the circle. This force may be the tension of a string, *ca*, or the attraction between a planet at *c* and its moon *a*, or the inward pressure of the rails, *a b*, on a curve, etc., etc. Like all force, it is an action between *two* bodies, tending either to separate them or to draw them closer together, and acting equally upon both. (See Art 5 (*b*), p 332) In the case of the string, it *pulls* the body *a*, *toward* the center, *c*, and the nail or hand, etc., at *c*, toward the body at *a* or *b*, etc.; *i. e.*, *from* the center. In the case of a car on a curve it *pushes* the car *toward* the center, and the rails *from* the center. The pull or push on the *revolving* body *toward* the center is called the **centripetal force;** while the pull or push tending to move the *deflecting* body *from* the center is called the **centrifugal force.** These two "forces," being merely the two "sides" (as it were) of the same stress, are necessarily equal and opposite, and can only exist together. The moment the stress or tension exceeds the strength (or inherent cohesive force) of the string, etc., the latter breaks. The centripetal and centrifugal forces therefore instantly cease, and the body, no longer disturbed by a deflecting force, moves on, at a uniform velocity,* in a tangent, *at* or *bt'*, etc., to its circular path; *i. e.*, at right angles to the direction which the centrifugal force had at the moment it ceased.

(*a*). **A single revolving body**, *a*, Fig. 1. Let

f = the centrifugal or centripetal force, in pounds.
W = the weight of the body *a*, in pounds,
R = the radius *ca* of the path of the *center of gravity* of the body *a*, in feet,
v = the uniform velocity of the body *a* in its circular path *abd*, in feet per second,
n = the number of revolutions per minute,
g = the acceleration of gravity = say 32.2 feet per second per second,
$900\,g$ = about 28980.
π = circumference ÷ diameter = say 3.1416. π^2 = about 9.8696.

Then, for the **centrifugal force**, f:

If we have the velocity v in feet per second: $$f = W\frac{v^2}{R\,g}\dagger \quad \ldots \quad (1)$$

If we have the number n of revolutions per minute: $$f = W\frac{\pi^2 R n^2}{900\,g}\ddagger \quad \ldots \quad (2)$$

$$f = \text{about } .0003406\ W R n^2 \S \quad \ldots \quad (3).$$

---

* Neglecting friction, gravity, the resistance of the air, etc.

† For let *at*, Fig. 1, represent the amount and direction of the velocity v of the body at *a* in feet per second. Then at the end of one second the body will have reached the point *b* (the arc *ab* being made = *at*), and the amount and direction of its velocity at *b* will then be represented by the line *bt'* = *at* in length, but differing in direction. Drawing *cu* and *cu'* at the center, equal and parallel respectively to *at* and *bt'*, we find that the *change in the direction* of the motion (*i. e.*, the acceleration toward the center) during the second is represented by the arc *uu'*; and, since angle *acb* = angle *ucu'*, we have the proportion, radius R or *ac* : *ab* or *at* : : *cu* or *at* : arc *uu'*. In other words, the acceleration *uu'* in one second, or rate of acceleration, is = $\frac{at^2}{R} = \frac{v^2}{R}$; and, for the force causing that acceleration, we have

$$f = \text{mass of body} \times \text{rate of acceleration} = \text{mass of body} \times \frac{v^2}{R} = W\frac{v^2}{R\,g}.$$

‡ By formula (1), $f = W\frac{v^2}{R\,g}$. But $v = \frac{2\,\pi\,R\,n}{60}$; and $v^2 = \frac{4\pi^2 R^2 n^2}{3600} = \frac{\pi^2 R^2 n^2}{900}$.

Hence, $f = W\frac{\pi^2 R^2 n^2}{900\,R\,g} = W\frac{\pi^2 R n^2}{900\,g}$.

§ Formula (3) is obtained from (2) by substituting the values 9.8696 and 28980 for π^2 and $900\,g$ respectively.

(b) Wheels and discs. Suppose the rim of a wheel to be cut into very short slices, as shown (much exaggerated) at a, Fig. 2. Then for each slice, as a, by formula (1): $f =$ weight W of slice $\times \frac{v^2}{R\,g}$;* and if each slice were connected

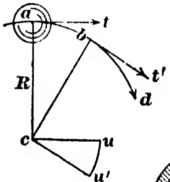

Fig. 1

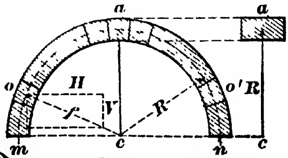

Fig. 2

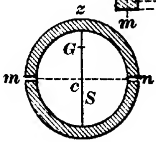

Fig. 3

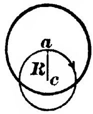

Fig. 4

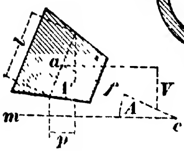

Fig. 5

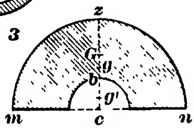

Fig. 6

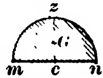

Fig. 7

with the center by a separate string, the sum of the stresses in all the strings (neglecting friction between adjacent slices) would be ·

$F =$ sum of centrifugal forces of all the slices † = weight of *rim* $\times \frac{v^2}{R\,g}$ . . . (4).

But the stress with which we are usually concerned in such cases (viz: **the tension in the rim itself** in the direction of a tangent to its own circumference) is *much less* than the theoretical quantity F obtained from formula (4), being in fact only $\frac{1}{6.2832}$ of it. For suppose first that the same thin rim is cut only at two opposite points m and n, Fig. 3, and that its two halves are held together only by the string S.

---

* If the rim is very thin in proportion to its diameter mn, we may take the center of gravity of each slice as being in a circle mn midway between the inner and outer edges of the rim, so that $R = \frac{\text{inner radius} + \text{outer radius}}{2}$. In a rim of appreciable thickness, this is not the case, because each slice is a little thicker at its outer than at its inner end. See Fig. 5. Hence its center of gravity is a little outside of the curved line mn, Fig. 2.

† In a perfectly balanced rim (*i. e.*, a rim whose center of gravity coincides with its center of rotation, as in Fig. 3) the centrifugal forces of the particles on one side of c counterbalance those on the opposite side. Here, too, $R = 0$. Hence, *as a whole*, such a rim has *no centrifugal force*; *i. e.*, no tendency to leave the center in any one direction by virtue of its rotation. But if the two centers do *not* coincide (Fig. 4), then the rim is a single revolving body, and its centrifugal force is: $f =$ weight of entire rim $\times \frac{v^2}{R\,g}$; where R is the distance between the two centers, and v the velocity of the center of gravity a. The force f acts in the line joining the two centers.

Then:*

semi-circumference mzn : diameter mn :: $\frac{F}{2}$: pull on the string S;

so that

$$\textbf{pull on string } S = \frac{\text{half weight}}{\text{of rim}} \times \frac{v^2}{R\,g} \times \frac{2}{\pi} = \frac{\text{weight}}{\text{of rim}} \times \frac{v^2}{R\,g\,\pi} = \frac{F}{\pi} = \frac{F}{3.1416} \quad \ldots (5)$$

and if the rim is now made complete by joining the ends at m and n, and if the string S is removed, then the pull on the string by formula (5) will be equally divided between m and n. Hence each cross-section, as m or n, of the rim, will sustain a tensile stress equal to half the pull on the string; or

$$\textbf{tension in rim} = \frac{F}{2\pi} = \frac{F}{6.2832} = \frac{\text{weight of rim} \times v^2}{6.2832\ R\,g} \quad \ldots\ldots\ldots \quad (6).$$

The centripetal force, f, Fig. 2, holding any part o of the rim to its circular path, is the resultant of the two equal tensions at the ends of that part.

For the *stress per square inch* of cross-section of rim, we have:

$$\textbf{unit stress} = \frac{\text{tension in rim}}{\text{area A of cross-section of rim, in square inches}}$$

$$= \frac{F}{6.2832\ A} = \frac{\text{weight of rim} \times v^2}{6.2832\ A\ R\,g} \quad \ldots\ldots \quad (7).$$

We shall arrive at the same result if we reflect that the pull in the string S, or the *sum* of the two tensions at m and n, is equal to the centrifugal force f of either *half* of the rim, revolving, as a single body, about the center c. Find the center of gravity G of the half rim, and then, in formula (1), use the velocity of that point, and the radius cG instead of velocity at z and radius cz respectively; thus:

$$\text{pull in string} = f = \frac{\text{centrifugal force}}{\text{of half-rim}} = \text{weight of half-rim} \times \frac{(\text{velocity at G})^2}{cG \times g},$$

and half of this is the tension in each cross-section of the rim.†

If the rim were infinitely thin, cG, Fig. 3, would be 0.6366 cz.

If its thickness must be taken into consideration, and if it is of rectangular cross-section find the centers of gravity g and g', Fig 6, of the whole semicircular segment cz and of the small segment cb respectively (cg = 0.4244 cz, and cg' = 0.4244 cb. Then

$$g'G = gg' \times \frac{\text{area of entire segment } cz}{\text{area of half rim}}.$$

For rims of other than rectangular cross-section, use formulæ (4), (5) and (6)

In a disc, such as a grindstone, the tension in each full cross-section mn, Fig. 7, is equal to the centrifugal force f of *half* the disc. Let W = weight of half disc. The distance cG from the center c to the center of gravity G of the half disc, is cG = 0.4244 cz; and the

---

* In Fig. 2, let the centrifugal force of any slice, o, be represented by the diagonal, f, of a rectangle, whose sides, H and V, are respectively parallel and perpendicular to the given diameter mn. Then H and V represent the components of f in those two directions. The equal and opposite horizontal components H, of o and of the corresponding slice o', being parallel to mn, have no tendency to pull the rim apart at m or n. Hence, the pull on a string S, Fig. 3, perpendicular to mn, is the sum of the components V of all the slices For each very thin slice, Fig. 5 (greatly exaggerated) we have (since angle A = angle A'):

Length l of slice : its horizontal projection, p :: centrifugal force f, of slice : its vertical component V.

Hence, for the entire half-rim mn, Fig. 3 (made up of such slices), we have:

Length mzn of half-rim : its horizontal projection mn :: the sum of the centrifugal forces of all the slices of the half-rim, : the sum of the vertical components V for all those slices;

which is identical with the proportion at top of page.

† The *rims* of revolving wheels are usually made strong enough to resist the tension due to the centrifugal force, without aid from the *spokes*, which thus have merely to support the *weight* of the wheel. But if the rim *breaks*, the centrifugal forces of its fragments come entirely upon the spokes; and, since the breakage is always irregular, some of the spokes will always receive more than their share.

$$\textbf{tension in } mn = \mathbf{f} = W\frac{(\text{vel. at G})^2}{\text{rad. }cG\times g} = W\frac{0.4244^2\,(\text{vel. at }z)^2}{0.4244\;cz\times g}$$

$$= W\frac{0.4244\,(\text{vel. at }z)^2}{cz\times g}\quad\ldots\ldots(8).$$

$$= W\frac{0.4244\,\pi^2\;n^2\;cz}{900\,g}\quad\ldots\ldots\ldots(9).$$

The stress *per square inch* in any full section mn is

$$\textbf{unit stress} = \frac{\text{tension in }mn}{\text{area of cross-section in square inches}},$$

$$= W\frac{0.4244\,(\text{velocity at }z)^2}{\text{diam. }mn\text{, ins.}\times\text{thickness, ins.}\times cz\times g}\quad\ldots(10).$$

$$= W\frac{0.4244\,\pi^2\,n^2\,cz}{\text{diam. }mn\text{, ins.}\times\text{thickness, ins.}\times 900\,g}\quad\ldots(11).$$

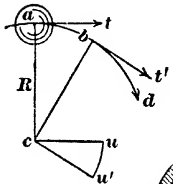

Fig. 1

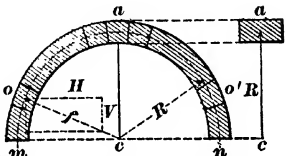

Fig. 2

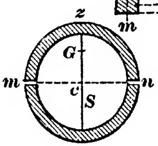

Fig. 3

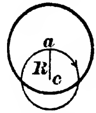

Fig. 4

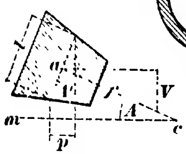

Fig. 5

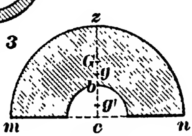

Fig. 6

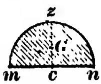

Fig. 7

f = the centripetal force, in pounds acting upon a single revolving body, a, Figs. 1, 2, 4 and 5, or upon the half-rim or half-disc, Figs. 3, 6 and 7 the centrifugal force exerted by such body

F = the sum of the centrifugal forces f, of all the particles of a rim, Fig. 3.

W = the weight of the body, in pounds.

R = the radius ca, Figs 1, 4 and 5, of the path of the *center of gravity* of the body.

v = the uniform velocity of the body in its circular path, in feet per second.

n = the number of revolutions per minute.

g = the acceleration of gravity = say 32.2 feet per second. 900 g = about 28980.

$\pi = \frac{\text{circumference}}{\text{diameter}}$ = say 3.1416 π^2 = about 9.8696

In a rolling wheel, each point in the rim, during the moment when it touches the ground, is stationary *with respect to the earth;* but each particle has the same velocity *about the center* as if the latter were stationary, and hence the centrifugal force has no effect upon the weight.

STATICS.

FORCES.

1. Statics Defined. The science of statics, or of equilibrium of forces, takes account of those very numerous cases where the forces under consideration are in equilibrium, or balanced. It embraces, therefore, all cases of bodies which are said to be "at rest."*

2. In the problems usually presented in civil engineering, a certain given force, or certain given forces, applied to a stationary * body (as a bridge or building) tend to produce motion, either in the structure as a whole or in one or more of its members; and it is required to find and to apply another force or other forces which will balance the tendency to motion, and thus permit the structure and its members to remain at rest. See ¶ 33, below.

3. Equilibrium. Suppose a body to be acted upon by certain forces. Then those forces are said to be in equilibrium, when, as a whole, they produce no change in the body's state of rest or of motion, either as regards its motion as a whole along any particular line (motion of translation), or as regards its rotation about any point, either within or without the body. In such cases the body also is said to be in equilibrium. See ¶ 84, below.

4. A body may be in equilibrium as regards the forces under consideration, even though not in equilibrium as regards other forces. Thus, a stone, held between the thumb and finger, is in equilibrium as regards their two equal pressures, even though it may be lifted upward by the excess of the muscular force of the arm over the attraction between the earth and the stone. Similarly, on a level railroad, a car is in equilibrium as regards gravity and the upward resistance of the rails, although the horizontal pull of the locomotive may exceed the resistance to traction.

5. Molecular Action. Any force, applied to a body, is in fact made up of a system of forces, often parallel or nearly so, applied to the several particles of the body. Thus, the attraction exerted by the earth upon a grain of sand or upon the moon is, strictly speaking, a cluster of nearly parallel forces exerted upon the several particles of those bodies; but, for convenience, and so far only as concerns their tendency to move the body as a whole, we conceive of such forces as replaced by a single force, equal to their sum and acting in one line. In thus considering the forces, we assume that the bodies are absolutely rigid, so that each of them acts as a single "**material particle**" or "**material point.**"

6. Transmission of Force. The upward pressure of the ground, upon a stone resting upon it, acts directly only upon those particles which are nearest to the ground. These, in turn, exert a (practically) equal upward force upon those immediately above them, and so on; and the force is thus transmitted throughout the stone.

7. Rigid Bodies. In treating of bodies as rigid, we assume that the intermolecular forces hold the several particles absolutely in their original relative positions.

It is not the *material* that resists being broken, but the *forces* which hold its particles in their places. Thus, a cake of ice may sustain a great pressure; but its particles yield readily when its cohesive forces are destroyed by a melting temperature.

8. Force Units. The force units generally used in statics are those of weight, as the pound and the kilogram. See Conversion Tables, p 235.

In statics we have no occasion to consider the masses of bodies (except

---

* Strictly speaking, *absolute* rest is scarcely conceivable, since all bodies are actually in motion (see Art. 3, p. 331), so that unbalanced forces produce merely *changes in the states of motion* of bodies. Yet, for a body to be at rest, *relative to other bodies*, is a very common condition, and, in practical statics, we usually regard the body under consideration as being at rest relatively to the earth or to some other large body, so that the change of state of motion, due to the action of unbalanced force upon it, consists in a change from relative rest to relative motion. See ¶ 33, below.

in so far as these determine their weights, or the force of gravity exerted upon them), bodies being regarded merely as the media upon and through which the forces under consideration are exerted. Hence we require, in statics, no units of mass; and, as the bodies are regarded as being "at rest," no units of time, velocity, acceleration, momentum, or energy.

9. Forces, how Determined. A force is fully determined when we know (1) its amount (as in pounds, or in some other weight unit), (2) its direction, (3) its sense (see ¶ 10), and (4) its position or its point of application.

10. When a force is represented by a line, the length of the line may be made to represent by scale the amount of the force, and its direction and position may often be made to indicate those of the force, while the sense of the force may be shown by arrows or letters affixed to the lines, or by the signs, + and —.

Thus, the *directions* of the forces represented by lines *a* and *b*, Fig. 1, are vertical, and those of *c* and *d* are horizontal. The *sense* of *a* is upward, of *b* downward, of *c* right-handed, of *d* left-handed. Thus, *a* and *b* are of like direction, but of opposite sense; and so with *c* and *d*. In treating of vertical or horizontal forces, we usually call upward or right-handed forces **positive,** and downward or left-handed forces **negative,** as indicated by the signs, + and —, in Fig. 1. When a force is designated by two letters, attached to the line representing it, one at each end of the line, the sense of the force may be indicated by the order in which the letters are taken. Thus, in Fig. 1, having regard to the directions of the arrows, we have forces, *e f*, *h g*, *k l*, and *n m*.

11. Line of Action, etc. The point (see ¶ 5) at which a force P, Fig 2, is supposed to be applied, as *a*, is called its point of application. But the force is transmitted, by the particles, throughout the body (see ¶ 6), and

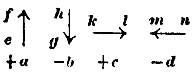

Fig. 1.

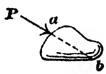

Fig. 2.

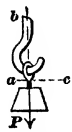

Fig. 3.

the effect of the force, as regards the body as a whole, is not changed if it be regarded as acting at any other point, as *b*, in its line of action. We may therefore regard any point in that line as a point of application of the force. For instance, the tendency to move the stone, Fig. 2, as a whole, will not be changed if, instead of *pushing* it, at *a*, we apply a *pull* (in the same direction and in the same sense) at *b*; and if a weight, P, be laid upon the top of the hook, at *b*, Fig. 3, it will have the same tendency, to move the hook as a whole, as it has when suspended from the hook as in the Fig.

A force cannot actually be applied to a body at a point outside of the substance of the body, as between the upper and lower portions of the hook in Fig. 3, yet this portion also of the line *a b* is a part of the line of action of the force. The vertical force, exerted by the weight, P, is transmitted to *b* by means of bending moments in the bent portion of the hook.

12. Stress. (See Art. 1, Strength of Materials, p. 454.) Opposing forces, applied to a body by contact (see Art. 5 c, p. 332), cause stress, or the exertion of intermolecular force, within it, or between its particles, tending to pull them apart (tension) or to press them closer together (compression). **The stress, due to two equal opposing forces,** is equal to *one* of them.

Tension and Compression. Ties, Struts, etc. If the action of the forces tends to pull farther apart the particles of the body upon which they act, the stress is called a tension or pull, or a tensile stress. If it tends to press them closer together, the stress is called a pressure, compression or push, or a compressive stress. A long slender piece sustaining tension is called a tie. One sustaining compression is called a strut or post. One capable of sustaining either tension or compression is called a tie-strut or strut-tie

MOMENTS.

13. Moments. If, from any point, o, or o', Fig. 4, a line, $o\,c$ or $o'\,s$, be drawn normally to the line of action, $n\,m$, of a force, P_1, whether the point, o or o', be within or outside of the body upon which the force, P_1, is acting, said line, $o\,c$ or $o'\,s$, is called the **arm** or **leverage** of the force about such point; and if the amount of the force, in lbs., etc., be multiplied by the length of the arm, in ft., etc., then the product, in ft.-lbs., etc., is called the **moment** of the force about that point.* The moment represents the total tendency of the force to produce rotation about the given point. A force has evidently no moment about any point in its line of action.

14. Sense of Moments. Since the moment of P_1 about o, Fig. 4, tends to cause rotation (about that point) in the direction of the motion of the hands of a clock, as we look at the clock and at the figure, or from left to right, as indicated by the arrow on the circle around o, it is called a **clockwise** or **right-hand** moment; but the moment of the same force about o' tends to produce rotation from right to left. Hence it is called a **counter-clockwise** or **left-hand** moment, as is also that of P_2 about o. Right-hand or clockwise moments are conventionally considered as **positive**, or +, and left-hand or counter-clockwise moments as **negative**, or —.

15. The plane of a moment is that plane in which lie both the line of action and the arm of the force.

16. The resultant or combined tendency of two or more moments in the same plane is equal to the algebraic sum of the several moments. Thus, Fig. 4, if the forces, P_1, P_2, and P_3, are respectively 6, 5, and 3 lbs., and if the arms, $o\,c$, $o\,y$, and $o\,e$, of their moments about o are respectively 7, 6, and 3 ft., we have

$$\begin{aligned} & P_1 . o\,c - P_2 . o\,y + P_3 . o\,e \\ &= 6 \times 7 - 5 \times 6 + 3 \times 3 \\ &= 42 - 30 + 9 = 21 \text{ ft-lbs.} \end{aligned}$$

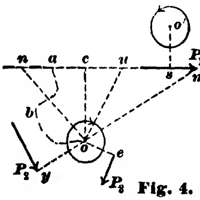

Fig. 4.

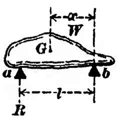

Fig. 5.

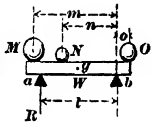

Fig. 6.

17. If the algebraic sum of the moments is zero, they are in **equilibrium** and tend to cause no rotation of the body about the given point.

Thus, in Fig. 5, where W is the weight, and G the center of gravity of the body, and R the upward reaction of the left support, a, taking moments about the right support, b, we have $R\,l - W\,x =$ zero; or $R\,l = W\,x$. Hence, having W, x and l, to find R, we have $R = \frac{W\,x}{l}$.

Similarly, in Fig. 6, where W = weight of beam alone, and g, the center of gravity of W, is at the center of the span l, so that the leverage $b\,g$ of the weight of the beam about b, is $= \frac{l}{2}$, we take moments about b, thus:

$$R\,l + O\,o - W\frac{l}{2} - M\,m - N\,n = \text{zero; or}$$

$$R = \frac{M\,m + N\,n + W\frac{l}{2} - O\,o}{l}.$$

*Note that a very small force may have a great moment about a point, while a much greater force, passing nearer to the same point, may have a smaller moment about it; or, passing through the point, no moment at all.

In Fig. 7, where W is the weight of the beam itself, and w its leverage, taking moments about b, we have

$$+ R\,l + O\,o - N\,n - W\,w + M\,m = 0;$$

Hence, Reaction at a = $R = \dfrac{W\,w + N\,n - M\,m - O\,o}{l}$.

In any case, if W be the combined weight and G the common center of gravity, of the beam and its several loads, and x the horizontal distance of that center from the right support, b; and if l be the span, R the reaction of the left support, a, and R′ that of the right support, b, we have

$$R = \frac{W\,x}{l}; \text{ and } R' = W - R.$$

If $x = \frac{l}{2}$, R is $= \frac{W}{2} = R'$.

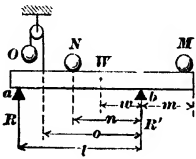

Fig. 7.

Note that the moments of two or more forces, about a given point, may be in equilibrium, while the forces themselves are not in equilibrium. See ¶ 84, below.

18. Center of Moments. So far as concerns equilibrium of moments, it is immaterial what point is selected as a center of moments; but it is generally convenient to take the center of moments in the line of action of one (or more, if there be concurrent forces, see ¶ 19) of the unknown forces, for we thus eliminate that force or those forces from the equation.

CLASSIFICATION OF FORCES.

19. Classification of Forces. Concurrent, Colinear, Coplanar, and Parallel Forces. Forces are called concurrent when their lines of

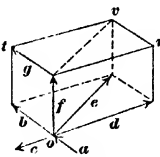

Fig. 8.

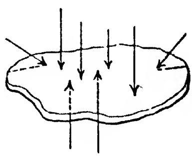

Fig. 9.

action meet at one point, as a, b, c, d, e and f, or f and g, Fig. 8; non-concurrent when they do not so meet, as c and g; colinear when their lines of action coincide, as a and b, or c and d; non-colinear when they do not coincide, as b and f; coplanar when their lines of action lie in one plane,* as a, b, c, d and e, or b, f and g, etc.; non-coplanar, as c and g, or b, f and d, when they do not lie in one plane; parallel when their lines of action are parallel, as b and g; non-parallel when those lines are not parallel, as b and f.

*Acting *upon* a plane, as in Fig. 9, must not be confounded with acting *in* that plane, as in Figs. 70, &c.

Any two parallel forces must be coplanar Three or more parallel forces may or may not be coplanar Any two concurrent forces must be coplanar. Three or more concurrent forces may or may not be coplanar Any two coplanar forces must be either parallel or concurrent

COMPOSITION AND RESOLUTION OF FORCES.

20. Resultant. A single force, which can produce, upon a body considered as a whole, the same effect as two or more given forces combined, is called the resultant of those forces Thus, in Fig 10 (*b*), a downward pressure, G, = *w* + W, is the resultant of the downward pressures *w* and W; and, in Fig. 11 (*b*), a downward pressure, = W — *w*, is the resultant of the downward pressure W and the upward pull *w* of the left-hand string *

21. Component. Any two or more forces which, together, produce, upon a body considered as a whole, the same effect as one given force, are called the components of that force, which thus becomes their resultant Thus, in Fig. 10 (*b*), *w* and W are the components of the total force, G, = *w* + W. In Fig. 11 (*b*), + W (= 5) and *w* (= — 3) are the components of G.*

22. If we take into account the resultant of any given forces, those forces (components) themselves must of course be left out of account, as regards their action upon the body as a whole; although we may still have to consider their effect upon its particles Vice versa, if the forces (components) are considered, their resultant must be neglected.

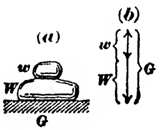

Fig. 10.

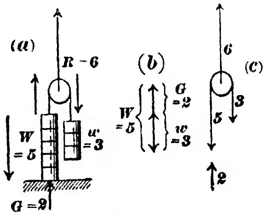

Fig. 11.

23. Anti-resultant. The anti-resultant of one or more forces is a single force which, acting upon any body or system of bodies considered as a whole, produces an effect equal, but opposite, to that of their resultant. In other words, tne anti-resultant is the force required to hold the given force or forces in equilibrium. Thus, in Fig. 10 (*b*), the upward reaction, G, of the ground, is the anti-resultant of the two downward forces, *w* and W; and the downward resultant, W + *w*, of W and *w*, is the anti-resultant of G. In Fig. 11 (*b*), G (upward) is the anti-resultant of W (downward) and *w* (acting upward through the left-hand string). Similarly, this upward pull of *w* is the anti-resultant of W and G.

24. In any system of balanced forces (forces in equilibrium), any one of the forces is the anti-resultant of all the rest; and any two or more of them have, for their resultant, the anti-resultant of all the rest. In such a system, the resultant (and the anti-resultant) of all the (balanced) forces is zero.

25. Anti-component. The anti-components of a given force, or of a given system of forces, are any two or more forces whose resultant is the anti-resultant of the given force or of the given system of forces.

26. Composition and Resolution of Forces. The operation of finding the resultant of any given system of forces is called the composition of forces; while that of finding any desired components of a given force is called the resolution of the force.

* For convenience, we here reverse the convention of ¶ 10.

Colinear Forces.

27. Let the vertical line, w, Fig. 10 (b), represent, by any convenient scale, the weight of the upper stone in Fig. 10 (a), and W that of the lower stone. Then, w + W, = G, = the combined length of the two lines, gives, by the same scale, the combined weight of the two stones, and a vertical line G, coincident with them, equal to their sum, and pointing upward, would represent their anti-resultant, or the reaction of the ground.

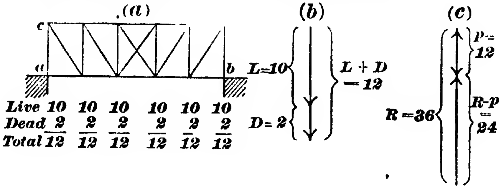

Fig. 12.

28. Similarly, if, at each panel point of the lower chord in the bridge truss in Fig. 12 (a). we have 2 tons dead load (weight of bridge and floor, etc.*) and 10 tons live load (train, vehicles, cattle, passengers, etc.), the combined length of the two lines in Fig. 12 (b), L = 10, and D = 2, gives the tota panel load of 12 tons.

29. In Fig. 11 the pressure, 5 lbs., of W upon the ground, is diminished by the 3 lbs. upward pull of the cord, transmitted from the smaller weight w, leaving 2 lbs. upward pressure to be exerted by the ground in order to maintain equilibrium. The upward reaction, R, of the pulley is = w + W — G = 3 + 5 — 2 = 6. This is represented graphically in Fig. 11 (c).

30. In the truss shown in Fig. 12 (a), the total dead and live load is = 6 × 12 = 72 tons, and half this total load, or 36 tons, rests upon each abutment. Hence, to preserve equilibrium, each abutment must exert an upward reaction of 36 tons; but, in order to ascertain how much of these 36 tons is *transmitted through the end-post, a c*, we must deduct from it the 12 tons which we assume to be originally concentrated, as dead and live load, at the panel point a; for this portion is evidently not transmitted through a c. Accordingly, in Fig. 12 (c), we draw R upward, and equal by scale to 36 tons; and, from its upper end, draw p downward and = 12 tons. The remainder of R, = R — p = 36 — 12 = 24 tons, is then the pressure transmitted through a c.

31. Colinear forces are called **similar** when they are of like sense, and **opposite** when of opposite sense. The same distinction applies to resultants.

Fig. 13.

32. For equilibrium, under the action of colinear forces, it is, of course, necessary that the sum of the forces acting in one sense be equal to the sum of those acting in the opposite sense, or, in other words, that the algebraic sum of all the forces be zero. Thus, in Fig. 13, if the forces are in equilibrium, the sum, b a + a o, of the two right-handed forces must be equal to the sum, e d + d c + c o, of the three left-handed forces. Or, considering the right-handed forces, b a and a o, as positive, and the left-handed forces, e d, d c and c o, as negative, as in ¶ 10, we have, as the condition of equilibrium of colinear forces:

$$b\,a + a\,o - o\,c - c\,d - d\,e = 0.$$

---

* The dead load is, of course, never actually concentrated upon one chord as here indicated; but it is often assumed, for convenience, that it is so concentrated.

In other words, the algebraic sum of all the forces must be zero; or, more briefly,

$$\Sigma \text{ forces} = 0,$$

where the Greek letter Σ (sigma), or sign of summation, is to be read "The sum of—."

33. Two equal and opposite forces, acting upon a body, are commonly said to keep it at rest; but, strictly speaking, they merely *prevent each other* from moving the body, and thus *permit* it to remain at rest, so far as they are concerned; for they cannot keep it at rest against the action of any third force, however slight and in whatever direction it may act; and the body itself has no tendency to move.

34. Unequal Opposite Forces. If two opposite forces, acting upon a body, are unequal, the smaller one, and an equal portion of the greater one, act against each other, producing no effect upon the body as a whole; while the remainder, the resultant, moves the body in its own direction.

Concurrent Coplanar Forces. The Force Parallelogram.

35. Composition. Let the two lines, $a\,o$, $b\,o$, in any of the diagrams of Fig. 14, represent, in magnitude, direction and sense, concurrent forces whose lines of action meet at the point o. Then, in the parallelogram, $a\,c\,b\,o$, formed upon the lines $a\,o$, $b\,o$, the resultant of those two forces is represented, in magnitude and in direction, by that diagonal, R, which passes through the point, o, of concurrence. The parallelogram, $a\,c\,b\,o$, is called a **force parallelogram.**

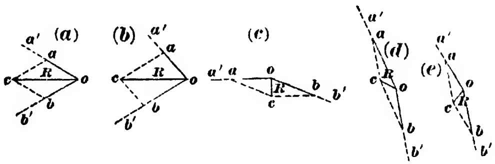

Fig. 14.

36. Resolution. Conversely, to find the components of a given force, $o\,c$, Fig. 14, when it is resolved in any two given directions, $o\,a$, $o\,b$, draw the lines, $o\,a'$, $o\,b'$, in those directions and of indefinite length, and upon these lines, with the diagonal $R = o\,c$, construct the force parallelogram $a\,c\,b\,o$. The sides, $o\,a$, $o\,b$, of the parallelogram then represent the required components in amount and in direction.

37. Caution. The two forces, $a\,o$ and $b\,o$, Fig. 14, may act either toward or from the point o; or, in other words, they may act either as pulls or as pushes; but the lines representing them in the parallelogram, and meeting at the point, o, must be drawn, either both as pushes or both as pulls; and the resultant, R, as represented by the diagonal of the parallelogram, will be a pull or a push, according as the two forces are represented as pulls or as pushes.

38. Thus, in Fig. 15 (a), the inclined end-post of the truss pushes obliquely downward toward o, with a force represented by $a'\,o$, while the lower chord pulls away from o, toward the right, with a force represented by $o\,b'$. If, now, we were to construct, in Fig. 15 (a), the parallelogram $o\,a'\,c'\,b'$, we should obtain the diagonal $o\,c'$ or $c'\,o$, which does not represent the true resultant. In fact, as one of the two forces acts toward, and the other from, the point, o, we could not tell (even if R′ were the *direction* of the resultant) in which *sense* its arrow should point.

We must first either suppose the push, $a'\,o$, in the end-post, toward o, to be carried on beyond o, so as to act as a pull, $o\,a$, Fig. 15 (b) (of course, in the same direction and sense as before), thus treating both forces as pulls; or

else we must similarly suppose the pull, *o b'*, in the chord, to be transformed into the push, *b o*, of Fig. 15 (*c*), thus treating both forces as pushes. In either case we obtain the true resultant, R (= *a' b'*, Fig. 15 *a*), which, in this case, represents the vertical downward pressure of the end of the truss upon the abutment.

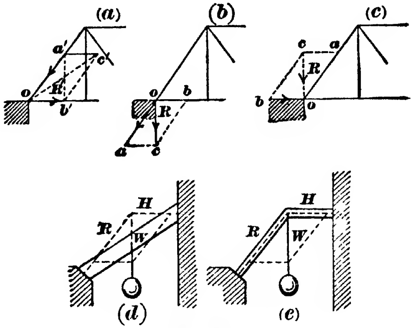

Fig. 15.

Caution. The tensile force, exerted at the end of a flexible tie, necessarily acts in the line of the tie; but, in general, the pressure, exerted at the end of a strut, acts in the line of the axis of the strut only when all the forces producing it are applied at the other end of the strut. Thus, in Fig. 15 (*d*), the components, R and H, of the weight, W, do not coincide with the axis of the beam which supports the load; but in Fig. 15 (*e*), where the weight acts at the intersection of the two struts, its components, R and H, do coincide with the axes of the struts. See also Figs. 143 and 145 (*b*).

39. Demonstration. The rational demonstration of the principle of the force parallelogram is given in treatises on Mechanics (See Bibliography.) It may be established experimentally as indicated in Fig. 16, where *c o* represents by scale the pull shown by the spring balance C, while *o a* and *o b* represent those shown by A and B respectively

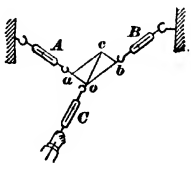

Fig. 16.

40. Equations for Components and Resultant. Given the amounts of the forces, *a* and *c*, or of the resultant, R, and the angles formed between them, Fig. 17 (*a*), we have*:

---

* See dotted lines, Fig. 17 (*a*), noting that $c' = c$; $c. \sin (x + y) = R. \sin x$, and $a. \sin (x + y) = R. \sin y$.

$$R = c\,\frac{\sin (x + y)}{\sin x} = a\,\frac{\sin (x + y)}{\sin y} = \sqrt{a^2 + c^2 + 2\,a\,c\,\cos (x + y)}$$

$$c = R\,\frac{\sin x}{\sin (x + y)};\quad a = R\,\frac{\sin y}{\sin (x + y)}.$$

If the angle between the two forces is 90°, Fig. 17 (*b*), these formulas become:

$$R = \frac{c}{\cos y} = \frac{a}{\cos x}$$

$$c = R \cos y;\quad a = R \cos x.$$

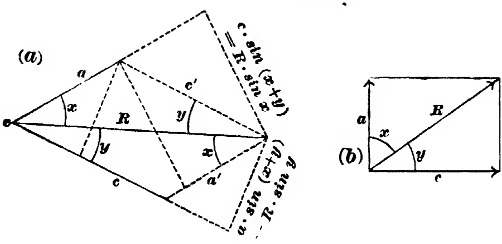

Fig. 17.

41. Position and Sense of Resultant. Figs. 18 If the lines representing the components be drawn in accordance with ¶¶ 37 and 38, and if a straight line, *m n* or *m' n'*, be drawn through the point, *o*, of concurrence, in such a way that both forces are on one side of that line, then the line representing the resultant will be found upon the same side of that line with the components, and between them; and it will act toward the line, *m n* or *m' n'*, if the components act toward it, and vice versa The resultant is necessarily in the same plane with its two components

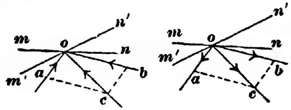

Fig. 18.

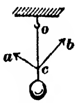

Fig. 19.

42. If one of the components is colinear with the force, it is the force itself, and the other component is zero. In other words, a force cannot be resolved into two non-colinear components, one of which is in the line of action of the force. Thus the rope, *o c*, Fig. 19, may receive assistance from *two* additional ropes, pulling in the directions *a c*, and *c b*; for the resultant of their pulls may coincide with *o c*; but, so long as *o c* remains vertical, no *single* force, as *c a* or *c b*, can relieve it, unless acting in its own direction *c o*.

43. In Fig 20, the load, P, placed at C, is suspended entirely by the vertical member B C, and exerts directly no pull along the horizontal member, C E. Neither does a pull in the latter exert any effect upon the force acting in B C, so long as B C remains vertical. But the tension in B C, acting at B, does exert a thrust *o a* along B D, although that member is at right angles to B C; for B C meets there also the inclined member A B; and the tension *o d* is thus resolved into *o a* and *o b*, along B D and B A respectively. The horizontal thrust, *o a*, in B D, is really the anti-resultant of the horizontal component, *d b*, of the oblique thrust in the end-post B A at its head. B, which thrust is = the pull in A E, due to P.

44. In Fig. 21, the tension, *o c*, in the inclined tie, D G, is resolved, at D into *o a* and *o b*, acting at right angles to each other along D F and D E respectively.

45. A resultant may be either greater or less than either one of its two oblique components, but it is always less than their sum. If the components are equal, and if the angle between them = 120°, the resultant is equal to one of them. Therefore the same weight which would break a single vertical rope or post, would break two such ropes or posts, each inclined 60° to the vertical

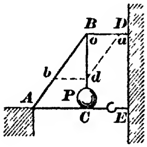

Fig. 20.

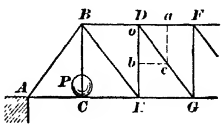

Fig. 21.

The Force Triangle.

46. The Force Triangle. Inasmuch as the two triangles, into which a parallelogram is divided by its diagonal, are similar and equal, it is sufficient to draw either one of these *triangles*, *a o c* or *b o c*, Figs. 14, 16, 18, instead of the entire parallelogram

47. If three concurrent coplanar forces are in equilibrium, the lines representing them form a triangle; and the arrows, indicating their senses follow each other around the triangle Thus, in Fig. 22 (*a*), we have, acting at *o* and balancing each other there, three forces: viz., (1) the vertical downward force *o c* of the weight, acting as a pull through the rope *o c*, (2) the horizontal thrust *a o* through the beam *a o*, and (3) the upward inclined thrust *b o* of the strut *o b*, all acting in the senses (*o c*, *a o*, *b o*) in which the letters are taken, and as indicated by the arrows.

48. Each of the forces in Fig. 22 (*b*) and (*c*) is the anti-resultant of the other two in the same triangle; and, if its sense be reversed, it becomes their resultant. Thus, *o c*, Fig. 22 (*b*), is the anti-resultant, and *c o* the resultant of *c a* and *a o*; and *o c*, Fig. 22 (*c*), is the anti-resultant, and *c o* the resultant of *c b* and *b o*, *c b* being parallel to *a o*, Fig (*b*), and representing the thrust exerted by the horizontal beam against the joint *o*, Fig. (*a*).*

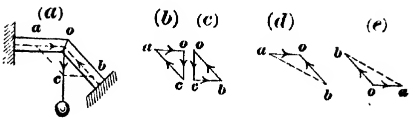

Fig. 22.

*Fig. 22 (*d*) and (*e*), representing the same two forces, *a o*, *b o*, of Fig 22 (*a*), show the erroneous resultant (*a b*) obtained if the lines are drawn with their arrows pointing both toward or both from the meeting-point of the lines. See ¶¶ 37, 38. A comparison of any force parallelogram, as that in Fig. 18, with either of the two force triangles composing it, will show that this, while apparently contradicting ¶¶ 37 and 38, is merely another statement of the same fact The apparent contradiction is due to the fact that, in the force triangle, the lines representing the forces do not meet at the point, *o*, of concurrence of the forces.

49. Conversely, if the three sides of a triangle be taken as representing, in direction and in amount, three concurrent forces whose senses are such that arrows, representing them and affixed to their respective sides in the triangle, follow each other around it, then those forces are in equilibrium.

50. The three forces, Fig. 23, are proportional, respectively, to the sines of their opposite angles. Thus:

Force a : force b : force c
= Sin A : sin B : sin C.

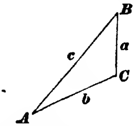

Fig. 23.

51. Example. In Fig. 24, the half arch and its spandrel, acting as a single rigid body, are assumed to be held in equilibrium by their combined weight, W, the horizontal pressure h at the crown, and the reaction R of the skewback, which is assumed to act through the center of the skewback. In the force triangle $c\ s\ t$, $c\ s$, acting through the center of gravity of the half arch and spandrel, represents the known weight W, and $s\ t$ is drawn horizontal, or parallel to h. From c, where h, produced, meets the line of action of W, draw $c\ t$ through the center of the skewback. Then $s\ t$ and $c\ t$ give us the amounts of h and R respectively.

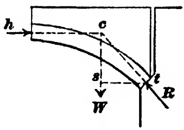

Fig. 24.

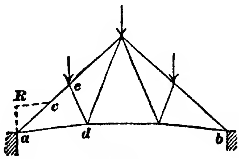

Fig. 25.

52. Example. Let Fig. 25 represent a roof truss, resting upon its abutments and carrying three loads, as shown by the arrows. Draw a R vertically, to represent the proportion of the loads carried by the left abutment, a, or, which is the same thing, the vertical upward reaction of that abutment. Then, drawing R c, parallel to the chord member, $a\ d$, to intersect $a\ e$ in c, we have, for the stresses in $a\ e$ and $a\ d$, due to the three loads:

Stress in $a\ e = a\ c$
" " $a\ d =$ R c

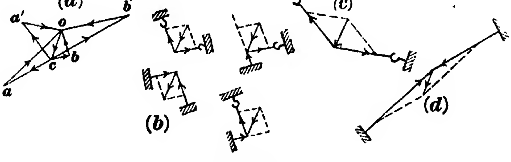

Fig. 26.

53. While any two or more given forces, as $o\ b$ and $b\ c$, Fig. 26 (a) (arrows reversed), or $o\ b'$ and $b'\ c$, or $o\ a$ and $a\ c$, or $o\ a'$ and $a'\ c$, can have but one resultant $o\ c$; a single force, as $o\ c$, may be resolved into two or more concurrent components in any desired directions. In other words, there is an infinite number of possible systems of concurrent forces which have $o\ c$ for their resultant.

Rectangular Components.

54. Resolutes, or Rectangular Components. A very common case of resolution of forces is that where a force, as the pressure, *c n*, of the post, Fig. 27, is to be resolved into components at right angles to each other, as are the vertical and horizontal components *c t* and *t n* in Fig. 27 (*a*). Two such components, taken together, are called the resolutes or rectangular components of the force. The joint, *o d*, in Fig. 27 (*a*), is properly placed at right angles to *c n*; but the joint *c i b*, Fig. 27 (*b*), provides also against accidental changes in the direction of *c n*. In Fig. 27 (*b*), the surfaces, *c i* and *i b*, are preferably proportioned as the components, *c t* and *t n*, Fig. 27 (*a*), respectively, by similarity of triangles, *c i b*, *c t n*.

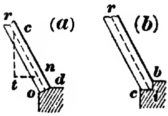

Fig. 27.

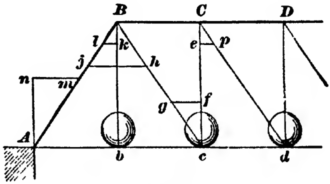

Fig. 28.

55. Example. In bridge and roof trusses it is often required to find the vertical and horizontal resolutes of the stress in an inclined member, or to find the stress brought upon an inclined member by a given vertical or horizontal stress applied at one of its ends, in conjunction with another stress (whose amount may or may not be given) at right angles to it.

Thus, in Fig. 28, the tension C *p* in the diagonal C *d* is resolved into a compression *e p* along the upper chord member C D* and a compression C *e* in the post C *c*.* Adding to C *e* the load at *c*, and representing their sum by *f c*, we have tension *f g* in chord member *c d*, and tension *c g* in the diagonal B *c*. Making B *h* = *c g*, we have *j h*, compression in B C, and B *j*, compression in the end-post or batter post B A. But the load at *b* also sends to B, through the hip vertical B *b*, a load (tension) equal to itself Representing this by B *k*, we have *l k* as its component along the chord member B C, and B *l* as its component along the end-post B A. Now, making A *m* = the sum of B *j* and B *l*, we find the vertical resolute A *n* = so much of the vertical reaction of the abutment as is due to the three loads only, and the horizontal resolute *m n* = the corresponding stress in the chord member, A *c*.

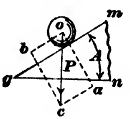

Fig. 29.

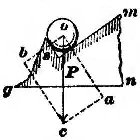

Fig. 30.

56. Example. Inclined Plane. Again, in Fig. 29, let it be required to find the two resolutes of P (the weight of the ball) respectively parallel and perpendicular to the inclined plane. The former is the tendency of the ball to move down the plane, and is called the **tangential component.** The

*The stress thus found is not necessarily the *total* stress in the member. The compression in C *c* (neglecting its own weight and that of the top chord) is due entirely to the tension C *p* in C *d*, acting at its top, and hence C *e* represents the total compression in C *c*; but *e p* is only a *portion* of the compression sustained by C D; for B C also contributes its share toward this.

latter is the pressure of the ball against the plane, and is called the **normal component.**

Here we have only to draw the triangle of forces *o a c*,* drawing *o c* = P to represent the weight of the ball, and *o a* and *a c* in the required directions. Then *o a* and *a c* give respectively the normal and the tangential components of the force, P.†

57. If we suppose the inclined plane *g m*, Fig 29, to be frictionless, and if the body *o* is to be prevented from sliding down the plane, by means of a force applied in a direction parallel to the plane, that force must be = *c a*.
Thus, in Fig. 30, supposing the plane *o m* to be frictionless, we have *a c* = pressure against the stop, *s*.

58. Table of normal and tangential components for different angles of inclination:

* Or *o b c*. If both triangles are drawn, we have the force parallelogram, *o a c b*.

†The line *a c* (or *c a*) is called the **projection** of *o c* upon the inclined plane; and *o a* (or *a o*) is the projection of *o c* upon a *normal* to the inclined plane

59. Equations. In Fig. 29,

$$o\ a = \mathrm{P} \,.\, \cos\ c\ o\ a$$
$$a\ c = \mathrm{P} \,.\, \sin\ c\ o\ a$$

and, since the angle $c\ o\ a$ between the vertical $o\ c$ and the normal component $o\ a$ is equal to the angle A of inclination between the plane $g\ m$ and the horizontal $g\ n$, we have.

$$\text{Normal component,} \quad o\ a = \mathrm{P} \,.\, \cos \mathrm{A}.$$
$$\text{Tangential component,} \quad a\ c = \mathrm{P} \,.\, \sin \mathrm{A}.$$

60. When a force is resolved into *rectangular* components, as in Figs. 29 and 30, each of these components represents the *total effort or tendency* which *that force alone* can exert *in that direction.*

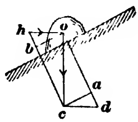

Fig. 31.

Thus, in Fig 31, the utmost force which the weight $o\ c$ alone can exert *perpendicularly against the plane* is that represented by the component $o\ a$. True, if, in order to prevent the body from sliding down the plane, we apply a force in some other direction, such as the horizontal one, $h\ o$, instead of the tangential one $b\ o$, and find the components of $o\ c$ in the directions $h\ o$ and $o\ a$, we shall find the normal component $o\ d$ greater than before; but the increase $a\ d$ is due entirely to the normal component, $h\ b$, of the horizontal force $h\ o$. Thus, the only effect upon the body o, and upon the plane, of substituting $h\ o$ for $b\ o$, is to add the normal component, $h\ b$, of the former, to that $(o\ a)$ of $o\ c$.

Stress Components.

61. Stress Components. In Fig. 32, let $a\ o$ and $b\ o$ be any two forces, and $c\ o$ their resultant. From a and b draw $a\ a'$ and $b\ b'$ at right angles to the diagonal $o\ c$ of the force parallelogram $a\ o\ b\ c$, and construct the sub-parallelograms (rectangles), $o\ a'\ a\ a''$ and $o\ b'\ b\ b''$. Each of the original components, $o\ a$, $o\ b$, is thus resolved into two sub-components, perpendicular to each other, one of which is perpendicular also to the resultant, $o\ c$, while the other coincides with $o\ c$ in position and in sense. Now, perpendiculars, let fall from the opposite angles of a parallelogram upon its diagonal, are equal,

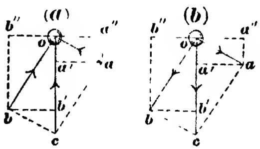

Fig. 32.

Hence the two colinear forces, $o\ a''$ and $o\ b''$, acting upon the body at o, are equal and opposite (although the lines, $a'\ a$ and $b'\ b$, representing them, are not opposite). Hence also they are in equilibrium, and their only effect upon the body is a stress of compression in Fig. 32 (a), and of tension in Fig 32 (b). They may therefore be called the stress components. The other two sub-components ($o\ a'$ of $o\ a$, and $o\ b'$ of $o\ b$) combine to form the resultant $o\ c$, which is equal to their sum, and which tends to move the body in its own direction.

62. The two great forces, $o\,a$, $o\,b$, in Fig. 33 (b) have the same resultant, $o\,c$, $=$ $o\,c'$, as the two small forces, $o\,a'$ $o\,b'$, in Fig. 33 (a), although their stress components, $a''\,a$, $=$ $b''\,b$, are much greater.

63. It often happens that one of the components is itself normal to the resultant. Thus, in Fig. 22, where $o\,c$ is vertical, its component, $o\,a$, is horizontal, and the perpendicular, let fall from a upon $o\,c$, represents its horizontal anti-component, $a\,o$. Here the horizontal and the inclined beam sustain equal horizontal pressures; but the vertical pressure, $o\,c$, $=$ the weight, W, is borne entirely by the inclined beam.

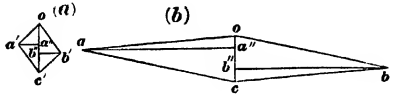

Fig. 33.

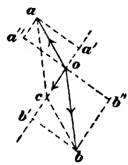

Fig. 34.

64. When, as in Fig. 34, the resultant, $o\,c$, forms, with one of the original components, $o\,a$ and $o\,b$, an angle, $a\,o\,c$, greater than 90°, the perpendiculars, $a\,a'$, $b\,b'$, from a and b, must be let fall upon the line of the resultant *produced*. Here, however, as before, the two equal and opposite sub-components, $o\,a''$ and $o\,b''$, are in equilibrium at o, while the other two sub-components, $o\,b'$ and $o\,a'$, go to make up the resultant $o\,c$; which, however (since $o\,b'$ and $o\,a'$ here act in *opposite* senses) is equal to their *difference*, and not to their sum, as in Fig. 32.

Fig. 34 shows that a *downward* force, $o\,c$, may be so resolved that one of its components is an *upward* force, $o\,a$, *greater* than the original *downward* force, and that the pressure, $o\,b$, has a component, $o\,b'$ or $b''\,b$, parallel to $o\,c$, and greater than $o\,c$ itself; for $b''\,b$ $=$ $o\,b'$ $=$ $o\,c$ $+$ $c\,b'$.

Applied and Imparted Forces.

65. Applied and Imparted Forces. In Fig. 29, the ball is free to roll down the inclined plane. Hence, although the entire weight P of the ball is *applied* to the body $g\,m\,n$, only the *normal component $o\,a$* is *imparted* to it or exerts any pressure upon it, and this pressure is in the direction $o\,a$.

But in Fig. 30, the body $g\,m\,n$ receives and resists not only the normal component $o\,a$, but also (by means of the stop s) the *tangential* component $o\,b$; and the entire force P, or $o\,c$, is thus *imparted* to the body $g\,m\,n$, pressing it in the direction $o\,c$.

Composition and Resolution of Concurrent Forces by Means of Co-ordinates.

66. In Fig. 35 (a) let the three coplanar forces E, F and G act through the point x. Draw two lines, H H, and V V, Fig. 35 (b), crossing each other at right angles, as at o.* These lines are called rectangular co-ordinates. From o, draw lines E o, F o, G o, parallel to E x, F x, G x, Fig. 35 (a), and equal respectively to the forces E, F, and G by any convenient scale. Resolve each of these forces, Fig. 35 (b), into two components, parallel to H H and V V respectively. Thus, E o is resolved into $t\,o$ and $n\,o$, F o into $u\,o$ and $e\,o$, G o into $i\,o$ and $m\,o$. Then, summing up the resolutes, we have:

Sum of horizontal resolutes $= u\,o - i\,o - t\,o = -\,s\,o$, and

Sum of vertical resolutes $= n\,o + e\,o - m\,o = a\,o$;

---

*It is only for convenience that the co-ordinates are usually drawn (as in Fig. 35) at right angles. They may be drawn at any other angle (see Fig. 36); but, in any case, the forces must of course be resolved into components *parallel to the co-ordinates*, whatever the directions of those co-ordinates may be.

and — *s o* and *a o* are the resolutes of the resultant, R, of the three forces, E, F and G.

67. When a system of (concurrent) forces is in equilibrium, the algebraic* sum of the components of all the forces, along either of the two co-ordinates, is zero. Thus, in Fig. 35 (*b*) or 36, if the sense of R be such that it shall act as the anti-resultant of the other three forces E, F and G, its component, *o s* or *o a*, along either co-ordinate, will be found to balance those of the other forces along the same co-ordinate.

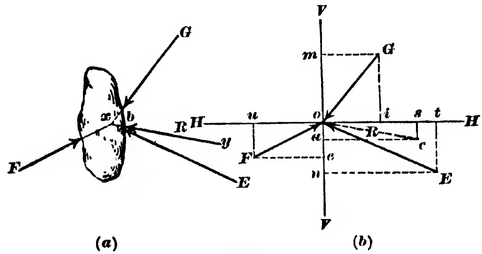

Fig. 35.

Hence we have the very important proposition that: When a system of concurrent coplanar forces is in equilibrium, the algebraic sums of their components, in any two directions, are each equal to zero.

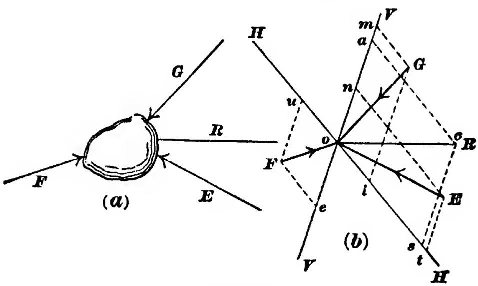

Fig. 36.

68. Conversely, in a system of concurrent forces, if the algebraic sums of the components in any two directions are each equal to zero, the forces are in equilibrium.

If the sum of the components in one of any two directions is not equal to zero, the forces cannot be in equilibrium. Thus, in Fig. 35 (*b*) or 36 (*b*), the sum of the components, along either one (as VV) of the two co-ordinates, may be zero; and yet, if the sum of those along the other co-ordinate is not zero, their resultant, or algebraic sum, will move the body, on which they act, in the direction of that resultant.

---

*The components being taken as + or —, according to the sense of each.

69. With vertical and horizontal co-ordinates, the condition of equilibrium* becomes:

The sum of the horizontal resolutes must be equal to zero;
The sum of the vertical resolutes must be equal to zero;

or, more briefly:

$$\Sigma \text{ horizontal resolutes} = 0$$
$$\Sigma \text{ vertical resolutes} = 0$$

Conversely, if these conditions are fulfilled, the forces are in equilibrium.

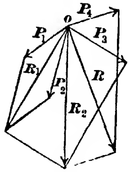

Fig. 37.

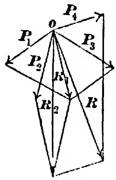

Fig. 38.

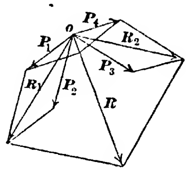

Fig. 39.

70. Resultant of More than Two Coplanar Forces. Where it is required to find the resultant of more than two concurrent and coplanar forces, as in Fig. 37, we may first find the resultant R_1 of any two of them, as of P_1 and P_2; then the resultant, R_2, of R_1 and a third force, as P_3; and so on, until we finally obtain the resultant R of all the forces. This resultant is evidently concurrent and coplanar with the given forces.

71. It is quite immaterial **in what order the forces are taken.** Thus, we may, as in Fig. 38, first combine P_1 and P_3; then their resultant R_1 with P_2, obtaining R_2; and, finally, R_2 with P_4, obtaining R; or, as in Fig 39, we may first combine any two of the forces, as P_1 and P_2, obtaining their resultant R_1; then proceed to any other two forces, as P_3 and P_4, and obtain their resultant R_2; and finally combine the two resultants, R_1 and R_2, obtaining the resultant R.

The Force Polygon.

72. The Force Polygon. Comparing Figs. 37 and 38 with Figs 40 and 41, respectively, we see that we may arrive at the same resultant R by simply drawing, as in Fig. 41, lines representing the several forces in any order, but following each other according to their senses. It will be noticed that this is merely an abbreviation of the process of drawing the several force parallelograms.

73. Resultant and Anti-resultant. The line,—R, required to complete the polygon, represents the *anti*-resultant of the other forces if its sense is such that it *follows* them around the polygon, as in Fig. 40. If its sense is *opposed* to theirs, as in Fig. 41, it is their *resultant*, R.

74. In other words, if any number of concurrent forces, as P_1, P_2, P_3, P_4 and R, Figs. 37 and 38,† are in equilibrium, the lines representing them, if drawn in any order, but so that their senses follow each other, will form a closed polygon, as in Fig. 40 (or in Fig 41 if the sense of R be reversed).

75. Conversely, if the lines representing any system of concurrent coplanar forces, when drawn with their senses following each other, form a closed polygon, as in Fig. 40, those forces are in equilibrium.

---

*With non-concurrent forces, another condition must be satisfied. See ¶ 83.

†R is here regarded as tending *upward*, so as to form the *anti*-resultant of the other forces.

It will be noticed that the force triangle, and the straight line representing a system of colinear forces, Figs. 10 and 11, ¶¶ 20, etc, or a system of parallel forces, Figs. 55, etc, ¶¶ 111, etc., are merely special cases of the force polygon.

76. In a force polygon, Fig. 42, any one of the forces is the anti-resultant of all the rest. Any two or more of the forces balance all the rest; or, their resultant is the anti-resultant of all the rest.

If a line *a c* or *b d*, Fig. 42, be drawn, connecting any two corners of a force

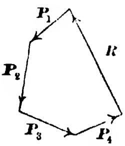

Fig. 40.

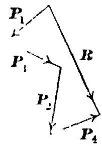

Fig. 41.

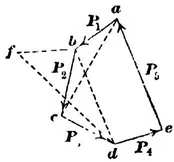

Fig. 42.

polygon, that line represents the resultant, or the anti-resultant (according as its arrow is drawn) of all the forces on either side of it. Thus:

a c	is the resultant of P_1 P_2	and the anti-resultant of	P_3 P_4 P_5
c a	" " " P_3 P_4 P_5	" "	" P_1 P_2
b d	" " " P_2 P_3	" "	" P_4 P_5 P_1
d b	" " " P_4 P_5 P_1	" "	" P_2 P_3

77. Knowing the *directions* of *all* the forces of a system, as $P_1 \ldots\ldots P_5$, Fig. 42, and the *amounts* of *all but two* of them, as P_2 and P_3, we may find the amounts of those two by first drawing the others, P_4, P_5 and P_1, as in the figure. Then two lines *b c* and *c d*, drawn in the directions of the other two and closing the polygon, will necessarily give their amounts

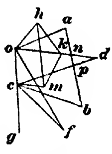

Fig. 43.

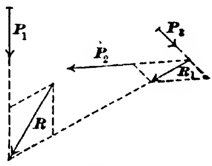

Fig. 44.

78. If any two points, as *o* and *c*, Fig 43, be taken, then the force or forces represented by any line or system of lines joining those two points will be equivalent to *o c*. Thus: *o c* = *o a b c* = *o d c* = *o n p c* = *o h k m c* = *o h m c* = *o f c* − *o g c*, etc, etc.

Similarly, in Fig 42, the force polygon *a b c d e a* is equivalent to the force polygon *a b f d e a*, and to the force triangle, *a b c a*, each being = zero.

Non-concurrent Coplanar Forces.

79. Non-concurrent Coplanar Forces. Fig 44. The process of finding the resultant of three or more coplanar but non-concurrent forces is the same as if they were concurrent. Thus, let P_1, P_2 and P_3 represent three such forces.* We may first find the resultant R_1 of any two of them, as P_2

*Any *two* coplanar non-parallel forces, as P_1 and P_2, or P_2 and P_3 are necessarily concurrent (see ¶ 19); but there is no single point in which the *three* forces meet.

and P_3; and then, by combining R_1 with the remaining force P_1, we find the resultant R of the three forces. Here the line R represents the resultant, not only in amount and in direction, but also in position. That is, the line of action of the resultant coincides with R.

80. The resultant R is the same, in amount and in direction, as if the forces were concurrent, and its position is the same as it would have been if their point of concurrence were in the line of R. If there are more than three forces, we proceed in the same way.

81. Conversely, the resultant R, or any other force, may be resolved into a system of any number of concurrent or nonconcurrent coplanar forces, in any directions, at pleasure. Thus, we may first resolve R into P_1 and R_1; then either of these into two other forces, as R_1 into P_2 and P_3, and so on.

82. If a system of non-concurrent coplanar forces is in equilibrium, the forces will still be in equilibrium if they are so placed as to be concurrent; provided, of course, that their directions, senses and amounts remain unchanged; but it does not follow that a system of forces, which is in equilibrium when concurrent, will remain in equilibrium when so placed as to be non-concurrent.

Thus, the five forces, $P_1 \ldots\ldots P_5$, Fig. 45 (*a*), may be so placed, as in Fig. 45 (*b*), that the resultant *a c*, of P_1 and P_2, does not coincide with the resultant *c a* of P_3, P_4 and P_5, but is parallel to it. These two resultants then form a couple. (See ¶¶ 155, etc.)

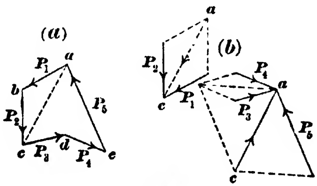

Fig. 45.

83. Third Condition of Equilibrium. Hence, the conditions of equilibrium for concurrent forces, stated in ¶ 69,

$$\Sigma \text{ vertical components} = 0$$
$$\Sigma \text{ horizontal components} = 0$$

do not suffice for non-concurrent forces, and a third condition must be added, viz.:—

$$\Sigma \text{ moments} = 0;$$

i. e., the moments of the forces, taken about any point, must be in equilibrium.

A system of forces in equilibrium has no resultant; hence it has no moment about any point. In other words, the moments of the forces, as well as the forces themselves, are in equilibrium.

84. The resultant of a system of unbalanced non-concurrent forces, acting upon a body, may be either

(1) a single force, acting through the center of gravity of the body; or

(2) a couple; *i. e.*, two equal and parallel forces of opposite sense (see ¶¶ 155, etc.); or

(3) either (a) a single force, acting through the center of gravity of the body, and a couple; or (b) a single force acting elsewhere than through the center of gravity of the body.

In Case (3), the two alternative resultants are interchangeable; *i. e.*, a single force, acting elsewhere than through the center of gravity of the body, may always be replaced by an equivalent combination consisting of an equal

parallel force, acting through the center of gravity of the body, and a couple, and vice versa. See ¶¶ 161, etc.

The resultant gives to the body, in Case (1), motion of translation in a straight line, without rotation; in Case (2), rotation without translation; and in Case (3), both translation and rotation. See foot-note (*), ¶ 1.

85. The force polygon, ¶ 72, Figs. 40, etc., and the method by coordinates, ¶ 66, Fig. 35, therefore, give us only the amount, direction and sense of the resultant of non-concurrent forces, and *not* its *position*. To find the position of the resultant of non-concurrent forces, we may have recourse to a figure, like Fig. 44, where the forces are represented in their actual positions, or to the cord polygon, ¶¶ 86, etc., Fig. 46.

The Cord Polygon.

86. In the force triangle any two of the three lines may be regarded as representing, by their directions, the positions of two members (two struts or two ties, or one strut and one tie) of indefinite length, resisting the third force; while their lengths give the amounts of the forces which those members must exert in order to maintain equilibrium.

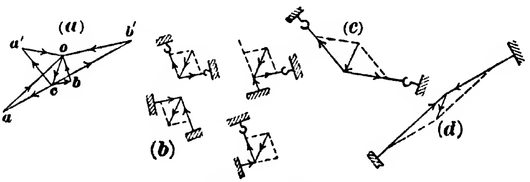

Fig. 26 (repeated).

87. Thus, in Fig. 26 (*b*), are shown four different systems, of two members each, inclined respectively like the forces *c b* and *b o* in Fig. 26 (*a*) and balancing the third force *o c*. The stresses in these two members are given by the lengths of the lines *c b* and *b o* in Fig. 26 (*a*).

The members acting as struts are represented, in Fig. 26 (*b*), as abutting against flat surfaces, while those acting as ties are represented as attached to hooks, against which they pull.

In Fig. 26 (*c*) and (*d*) are indicated systems of members, inclined like the forces *c a'* and *a' o*, *c a* and *a o*, respectively, of Fig 26 (*a*), by which the third force *o c* might be supported.

88. In the force polygon *a b c d e a*, Fig. 46 (*b*), representing the four forces, P_1, P_2, P_3, P_4, of Fig 46 (*a*), if we select, at pleasure, any point *o* (called the **pole**) and draw from it a series of straight lines *o a*, *o b*, etc. (called **rays**), radiating to the ends, *a*, *b*, *c*, etc., of the lines P_1, P_2, etc., representing the forces, we shall form a series of force triangles, *a o b*, *b o c*, etc.

Thus, in the triangle *a b o* we have the force P_1, or *a b*, balanced by the two forces *o a* and *b o;* in the triangle *b c o*, the force P_2, or *b c*, balanced by the two forces *o b* and *c o;* and so on.

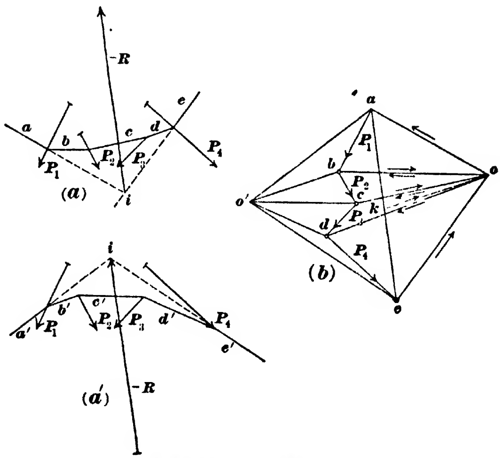
89. The Cord Polygon. If, now, in Fig. 46 (*a*), we draw the lines *a* and *b*, parallel respectively to the rays *o a* and *o b* of Fig 46 (*b*) and meeting in the line representing the force P_1, they will represent the positions of two tension members of indefinite length, which will balance the force P_1 by exerting forces represented, in amount as well as in direction, by the rays *o a* and *b o*, Fig. 46 (*b*). Again, taking pole *o'*, Fig. 46 (*b*), instead of *o*, we have *a'* and *b'*, Fig. 46 (*a'*), parallel respectively to the rays, *o' a* and *o' b*, and representing a pair of struts performing the same duty.

90. Similarly, the lines *b* and *c*, Fig. 46 (*a*), parallel respectively to rays *o b* and *o c*, represent two tension members, which, with stresses equal respectively to *o b* and *c o*, Fig. 46 (*b*), balance the force P_2.

91. We thus obtain, finally, a system of five tension members, *a b c d e*, Fig. 46 (*a*), which, if properly fastened at the ends *a* and *e* respectively, will, by exerting forces represented respectively by the rays, *o a*, *o b*, *o c*, etc., Fig. 46 (*b*), balance the four given forces P_1, P_2, P_3 and P_4.

92. The figure *a b c d e*, Fig. 46 (*a*), is called a cord polygon, funicular polygon, or equilibrium polygon.

93. Resultant, Anti-resultant. Amount and Direction. In the force polygon, Fig. 46 (*b*) or (*d*), the line *e a*, joining the end of the last force-line *d e* with the beginning of the first one *a b*, represents the anti-resultant of the given system of four forces, and *a e* their resultant. Evidently, therefore, the rays *a o* and *o e*, which represent two components of *a e*, represent also, in direction and in amount, two forces which would balance *e a*, or which would be equivalent to the given system of (four) forces.



Figs. 46 (*a*), (*a′*) and (*b*).

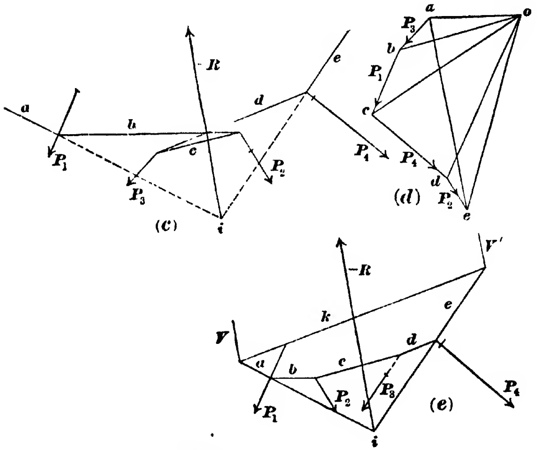
94. Position of Resultant. Hence, in the cord polygon, Fig. 46 (*a*), the intersection, *i*, of the cords *a* and *e*, parallel respectively to the rays *o a* and *e o*, is a point in the line of action of the resultant R; and, if we imagine *a i* and *e i* to be rigid rods, and apply, at *i*, a force, — R, equal and parallel to *a e*, but of opposite sense, that force will be the anti-resultant of the (four) given forces, and we shall have a frame work *b c d i* of cords and rods, kept in equilibrium by the action of the five forces, P_1, P_2, P_3, P_4 and — R.

95. The choice of position of the pole, *o*, in the force polygon, Fig. 46 (*b*), does not affect the resultant, R; but it does affect the shape of the cord polygon, Fig. 46 (*a*) or (*a′*). Thus, with the forces drawn in the order shown in (*b*), and with the pole, *o*, on the *right*, we obtain, as in Fig. (*a*), a series of supposed *ties*, *a*, *b*, *c*, etc.; but, with the pole, *o′*, on the *left* (forces drawn as before) we obtain a series of *struts*, *a′*, *b′*, *c′*, etc., Fig. (*a′*)

96. In constructing the cord polygon, Fig. 46 (*a*), (*a′*), (*c*), and (*e*), care must be taken to draw the cords in their proper places; and for this it is necessary to remember, simply, that the two rays pertaining to any particular force line in the force polygon, Fig. 46 (*b*), represent those members which, in the cord polygon, Fig. 46 (*a*), take the components of that force.

Thus, $o\ a$ and $b\ o$, Fig. 46 (b), pertain to the force P_1; $o\ b$ and $c\ o$ to the force P_2. Hence, in Fig 46 (a) or (c) we draw a and b (parallel respectively to $o\ a$ and $b\ o$) meeting in the line of action of P_1; b and c (parallel respectively to $o\ b$ and $c\ o$) meeting in the line of action of P_2, etc., etc.

97. Each ray in the force polygon, Fig. 46 (b), including the outside ones, is thus seen to pertain to two forces, and each force has two rays. The two cords, parallel respectively to the two rays of any force, must be drawn to meet in the line of action of that force; and each cord must join the lines of action of the two forces to which its parallel ray pertains. The lines, a, b, c, etc, in the *cord* polygon, Fig 46 (a) and (c), give merely the *inclinations* of members which, as there arranged, would sustain the given forces. The lengths of these lines have nothing to do with the amounts of the *stresses*. These are given by the lengths of the corresponding *rays* in the *force* polygon, Fig. 46 (b).



Figs. 46 (c), (d) and (e).

98. If the anti-resultant force, — R, is not applied, the cords a and e may be supposed fastened to firm supports, against which they exert stresses represented, in amount and in direction, by the rays $a\ o$ and $o\ e$, respectively. But the resistances of those two supports are plainly equal and opposite to those stresses, or equal to $o\ a$ and $e\ o$ respectively. Hence, their resultant is the anti-resultant, — R, of the four original forces.

99. If, Fig 46 (e), the two end members a and e were attached merely to two ties, V and V′, parallel to the anti-resultant, —R, they would evidently draw the ends of those ties inward toward each other. To prevent this, let the strut k be inserted, making it of such length that the ties V and V′ may remain parallel to — R, and draw $o\ k$, Fig. 46 (b), parallel to k. Then $a\ k$ and $k\ e$ give the stresses in V and V′ respectively.

100. If the anti-resultant, — R, found by means of the force polygon, be applied in a line passing through the intersection of the outer (initial and final) members in the cord polygon, all the forces, including of course the anti-resultant, will be in equilibrium. In other words, coplanar forces are in equilibrium if they may be so drawn as to form a closed force polygon, and if a closed cord polygon may be drawn between them. But if the anti-resultant be applied elsewhere, we shall have a couple, composed of the anti-resultant, — R, and the resultant R of the forces.

Concurrent Non-coplanar Forces.

101. Any two of the concurrent forces, as *o a* and *o c*, Fig. 47 (*a*) or (*b*), are necessarily coplanar. Find their resultant, *o r*, which must be coplanar with them and with a third force *o b* Then the resultant, R, of *o r* and *o b* is the resultant of the three forces. If there are other forces, proceed in the same way.

102. No three non-coplanar forces, whether concurrent or not, can be in equilibrium.

103. Force Parallelopiped. The resultant of any three concurrent non-coplanar forces, *o a*, *o b*, *o c*, Figs. 47, will be represented by the diagonal *o* R, of a parallelopiped, of which three converging edges represent the three forces.

104. Methods by Models. (a) For three forces. Construct a box, Fig. 47 (*a*) or (*b*), with three convergent edges representing the three forces in position and amount. Then a string *o* R, joining the proper corners, will represent the resultant.

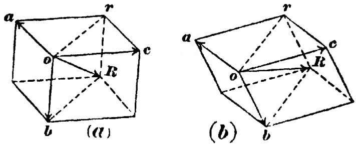


Fig. 47.

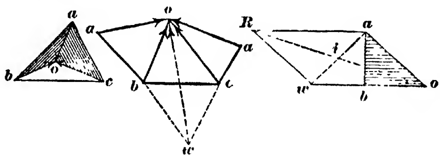
Or, let *a o*, *b o*, *c o*, Fig. 48 (*a*), be three forces, meeting at *o*. Draw on pasteboard the three forces *a o*, *b o*, *c o*, as in Fig. 48 (*b*), with their *actual* angles *a o b*, *b o c*, *c o a*, and find the resultant *w o* of the middle pair, *b o* and *c o*. Cut out neatly the whole figure, *a o a c w b a*. Make deep knife-scratches along *o b*, *o c*, so that the two outer triangles may be more readily turned at angles to the middle one. Turn them until the two edges *o a*, *o a* meet, and then paste a piece of thin paper along the meeting joint to keep



(*a*) (*b*) (*c*)

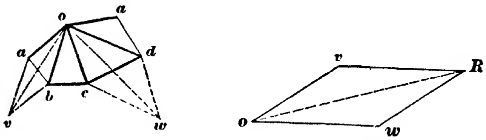
Fig. 48.

them in place. Stand the model upon its side *o b w c* as a base, and we shall have the *slipper* shape *a o b w*, Fig. 48 (*c*); *o w* being the sole, and *a o b* the hollow foot. In the model, the force *a o* and the resultant *w o* of the other two forces, are now in their actual relative positions To find their resultant, cut out a separate piece of pasteboard, R *a o w*, with R *a* and R *w* parallel respectively to *w o* and *a o*. Draw upon each side of it the diagonal R *o*. Paste this piece inside the model, with its lower edge *w o* on the line *w o*, Fig. 48 (*b*), and its edge *a o* in the corner *a o* This done, R *o* represents the resultant of *a o*, *b o*, *c o*, Fig 48 (*a*), in its actual position relative to them.

105. (b) For four forces, as *a o*, *b o*, *c o*, *d o*, in Fig. 49. Draw them as in Fig. 49 (*a*), with their angles *a o b*, *b o c*, etc. Draw also the resultants *v o*, of *c o* and *b o*; and *w o*, of *c o* and *d o*. Then cut out the entire figure, as before, and paste together the two edges *a o*, *a o*. Hold the model in such a way that two of its *planes* (as *a o b* and *b o c*) form the same angle with each other

as do the two corresponding planes between the forces. Then we have the two resultants $v\,o$, $w\,o$, Fig. 49 (*b*), in their *actual relative positions*. Cut out a separate piece of pasteboard R $v\,o\,w$, Fig. 49 (*b*), draw the diagonal R o on each side of it, and paste it inside the model, with $o\,v$ and $o\,w$ on the corresponding lines of the model. Then R o will represent the resultant of the four forces, $a\,o$, $b\,o$, $c\,o$, $d\,o$, in its actual position relative to them.

The model may be made of wood, the triangles $a\,o\,b$, $b\,o\,c$, etc., being cut out separately, the joining edges bevelled, and then glued together.



(*a*) **Fig. 49.** (*b*)

Non-concurrent Non-coplanar Forces.

106. Non-concurrent Non-coplanar Forces. Fig 50 (*a*). (For parallel non-coplanar forces, see ¶¶ 110, etc) Resolve each force into two rectangular components, one normal to an assumed plane, the other coinciding with the plane.* Find the resultant of the (coplanar) components coinciding with the plane, by methods already given, and that of the normal (parallel) components, by ¶¶ 110, etc. If these two resultants are coplanar, they are also concurrent, and their resultant (which is the resultant of the system) is readily found

107. If not, let V, Fig 50 (*b*), be the resultant normal to the plane, and H the resultant lying in the plane By ¶ 162, substitute, for H, the equal and parallel force H′, meeting V at O, and the couple H . O a, and find the resultant, R′, of V and H′ The system of forces is thus reduced to the single force R′ and the couple H . O a For Couples, see ¶ 155

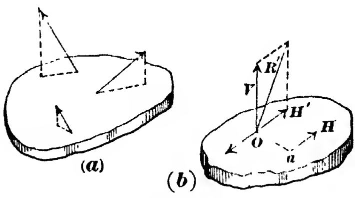


Fig. 50.

108. Moments of Non-coplanar Forces. The action of the weight W of the wall, Fig 51 (*a*), and of the non-coplanar forces P_1 and P_2, may be represented as in Fig. 51 (*b*), where the axle $a'\,c'$ represents the edge $a\,c$ about which the wall tends to turn, while the bars or levers represent the leverages of the forces. So far as regards the overturning stability of the wall, regarded as a rigid body and as capable of turning only about the edge $a\,c$, it is immaterial whether an extraneous force, as P_1, is applied at p or at q; but it is plainly not immaterial as regards a tendency to swing the wall around horizontally, or to fracture it; or as regards pressures (and consequent friction) between the axle $a'\,c'$ and its bearings. For equilibrium, $P_1\,m = P_2\,h + W.\,\frac{b}{2}$. Here a torsional or twisting stress is exerted in the axle,

*Wires, stuck in a board representing the plane, will facilitate this.

and the pressures of its ends in the bearings are more or less modified; but, so far as merely the equilibrium of the moments is concerned, we may suppose all of the forces and their moments to be shifted into one and the same plane, as in Fig. 51 (*c*).

109. In cases like that represented in Fig. 51, it is usual, for convenience, to restrict ourselves to a supposed vertical *slice*, *s*, 1 foot thick, and to the forces acting upon such slice; supposing the weight of the slice to be concentrated at its center of gravity, and the extraneous forces to be applied in the same vertical plane with gravity. In effect, we are then dealing with a slice indefinitely thin, but having the weight of the 1-ft. slice.

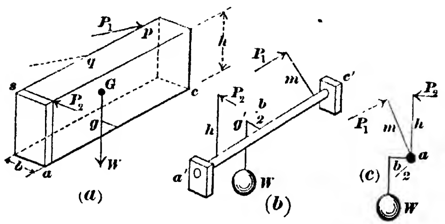

Fig. 51.

PARALLEL FORCES.

110. The resultant of any number of parallel forces, whether they are in the same plane or not, and whether in the same direction or not, is parallel to them and = their algebraic sum.

Coplanar Parallel Forces.

111. The resultant of any number of coplanar parallel forces is in the same plane with them, whether the forces are of the same or of opposite sense; and the leverages, or arms, of such forces, and of their resultant, about any given point in the same plane, are in one straight line. Thus, in Fig 56 (*a*), where the five forces, *a*, *b*, *c*, *d* and *e* are in one plane, their resultant, R, is in that same plane; and the leverages of the forces, and of R, about any point, as *b* or *v*, in the same plane, are in the straight line R *v*.

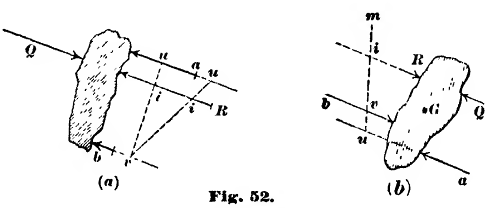

Fig. 52.

112. The resultant, R, or anti-resultant, Q, Fig. 52, **of two parallel forces,** *a* and *b*, intersects any straight line, *u v*, joining the directions of the two forces. Hence, if three parallel forces are in equilibrium, they are in the same plane. In Fig. 52 (*a*), the two forces, *a* and *b*, are of like sense. R is then between *a* and *b*, and R = *b* + *a*. In Fig. 52 (*b*), *a* and *b* are of opposite sense. R is then not between *a* and *b*, and R = *b* — *a*.

113. To find the position of the resultant, draw and measure any straight line, $u\,v$, joining the lines of action of the forces. It is immaterial whether $u\,v$ is perpendicular to said directions, or not. The line representing the resultant cuts $u\,v$, and its position is found thus:

$$u\,i = u\,v \times \frac{b}{\mathrm{R}}; \quad \text{and } v\,i = u\,v \times \frac{a}{\mathrm{R}}.$$

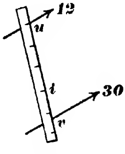

Fig. 53.

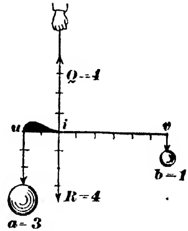

Fig. 54.

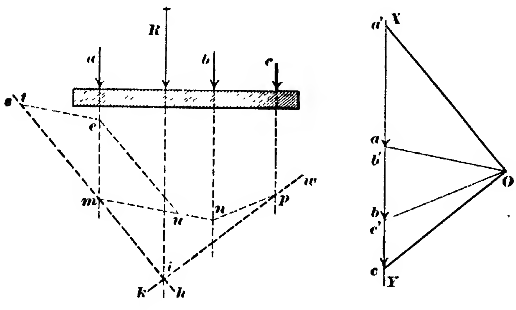
114. This may be conveniently done by making $u\,v$ equal, by any convenient scale, to the sum of the forces, as in Fig 53, where $u\,v = 42$. Then make $u\,i$ *equal*, by the same scale, to the force at v, or $v\,i$ equal to the force at u. Then a line, R, Fig 52 (a), drawn through i parallel to a and b, gives the position and direction of their resultant; and its *amount* is equal to the *sum* of a and b; or $\mathrm{R} = a + b$. In other words, if a force, Q, parallel to a and b, and equal to their sum, but of opposite sense, be applied to the body anywhere in a line passing through i, it will balance a and b, or will be their antiresultant.



(a) Fig. 55. (b)

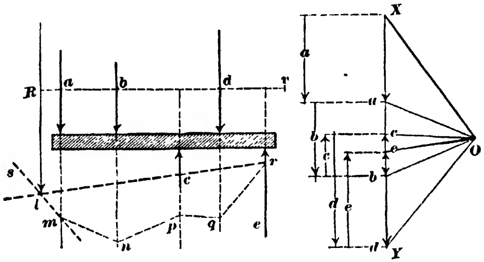
115. The position of the resultant, so found, satisfies the condition of equilibrium of moments: thus, $b.vi - a\,ui$ = zero.

If the two forces are equal, their resultant R is evidently midway between them.

116. In the common steelyard, Fig. 54, the two forces a and b, of Fig. 52 (a), are represented by the two weights, a = 3 pounds at u, and b = 1 pound at v, with leverages ui and vi respectively, as 2 : 6, or as 1 : 3.

It will be noticed that in Fig. 56 (*a*) the resultant, R, owing to the positions and amounts of the several forces, falls outside of the system of given forces.

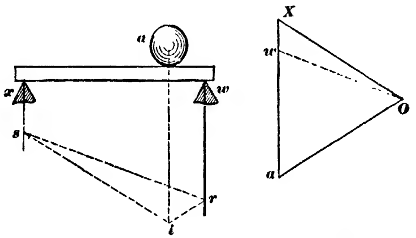
117. Figs. 55 to 58 illustrate the application of the cord polygon (¶¶ 86 to 100) to coplanar parallel forces. Here the force polygon is necessarily a straight line.



(*a*) (*b*)

Fig. 56.

118. Resolution. Let Fig. 57 (*a*) represent **a beam bearing a single concentrated load,** *a*, elsewhere than at its center; and let it be required to find the pressure on each of the two supports, *w* and *x*.



(*a*) (*b*)

Fig. 57.

Draw X *a*, Fig. 57 (*b*), to represent the load *a* by scale, and rays X O, *a* O, to any point O not in the line X *a*. In Fig. (*a*), from any point. *i*, in the vertical through the point, *a*, where the load is applied, draw *i s* and *i r*, parallel respectively to O X and O *a*. Join *r s*, and in Fig. (*b*) draw O *w* parallel to *r s*. Then the two segments, *w a* and X *w*, of X *a*, give by scale the pressures upon the two supports, *w* and *x* respectively. The greater pressure will of course be upon the support nearest to the load; but we may be guided also by remembering that the segment X *w*, adjoining the radial line O X in Fig. (*b*) represents the pressure on that support, *x*, Fig. (*a*), which pertains to the line *i s* parallel to O X; and vice versa.

119. Fig. 58 represents a case where there are several loads on the beam. Here the intersection, *i*, of the lines *h s* and *k r*, Fig. (*a*), drawn parallel respectively to O X and *c* O, Fig. (*b*) shows the position of the resultant of the three loads. Here, as in Fig. 57, we join *r s*, Fig. (*a*),

and draw O w, Fig. (b), parallel to $r\,s$. Then X w, Fig. (b), gives the pressure upon x, and $w\,c$ that upon w.

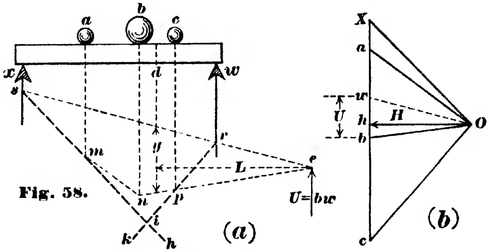


Fig. 58.

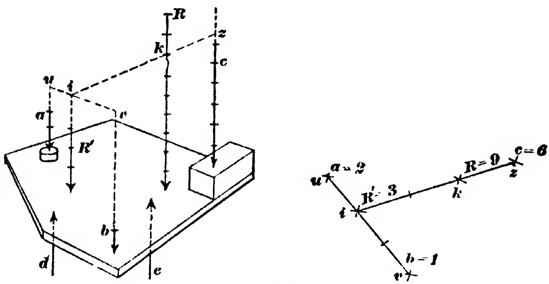
Non-coplanar Parallel Forces.

120. Non-coplanar Parallel Forces. Fig. 59 (a). Between the lines of action of any two of the forces, as a and b, draw any straight line, $u\,v$, and make

$$u\,i = u\,v \times \frac{b}{a+b}; \quad \text{or} \quad v\,i = u\,v \times \frac{a}{a+b}.$$

Through i draw R′, parallel to a and b, and equal to their sum. Then is R′ the resultant of a and b. Then, from any point, i, in the line of action of R′, draw $i\,z$ to any point, z, in the line of action of c, and make $i\,k = i\,z \times \frac{c}{c + R'}$; or $z\,k = i\,z \times \frac{R'}{c + R'}$. Through k draw R parallel to a, b and c, and equal by scale to their sum. Then is R the resultant of the three forces, a, b and c. If there are other forces, proceed in the same way with them.



(a) **Fig. 59.** (b)

121. In Fig. 59 (a) we have shown the forces, a and c, acting upon surfaces raised above the general plane, merely in order to illustrate the fact that it is not at all necessary that the forces be supposed to act upon or against a plane surface.

122. Although Fig. 59 (a) illustrates the method of finding the resultant of non-coplanar parallel forces, yet it plainly does not give the actual relative positions of the forces and their resultant; because it is necessarily drawn in a kind of perspective, and therefore all the parts cannot be measured by a scale. The true relative positions may of course be represented in plan, as by the five stars, a, b, c, i and k, Fig. 59 (b), corresponding to the points where

the forces and resultants intersect some one chosen plane. But it is now impossible to represent the forces themselves by lines. They must therefore be stated in figures, as is here done. It is then easy to find the positions of the resultants, as before

123. If there are also **forces acting in the opposite direction,** as d and e, Fig. 59 (a), find their resultant separately. We thus obtain, finally, two resultants of opposite sense. These resultants may be equal or unequal, and colinear or non-colinear. If they are non-colinear, see ¶ 84, and Couples, ¶¶ 155, etc.

124. Method by projections, Fig. 60. First find the projections, a', b' and c' of the forces, a, b and c, upon any plane, as $x\,y$, parallel to them; and then their projections, a'', b'', and c'', upon a second plane, $x\,v$, parallel to them and normal to the first. Find the position, R′, of the resultant of a', b' and c', in plane $x\,y$, and that R″, of a'', b'' and c'', in plane $x\,v$. Now, as the lines, a', b', c', and a'', b'', c'', are projections of the forces, a, b and c, so R′, R″, are projections of the resultant, R, of the forces. The position of R is therefore at the intersection of two planes, R R′ and R R″, perpendicular to the planes, $x\,y$ and $x\,v$, and standing upon the projections R′ and R″, of the resultant, R. R = $a + b + c$.

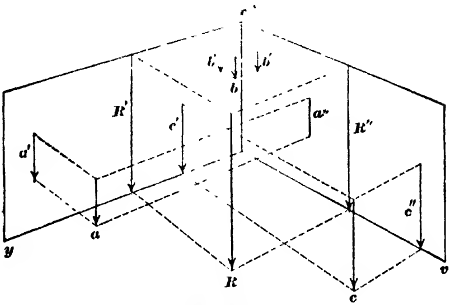


Fig. 60.

CENTER OF GRAVITY.

125. If a body, Fig. 1,* or a system of bodies, Fig. 2, be held successively in different positions, (a), (b), etc., the resultant of the parallel forces of gravity, acting upon its particles and indicated by the arrows in the figures, will occupy different positions, relatively to the figure of the body or system. That point, where all these positions, or lines of gravity, meet, is called the center of gravity of the body or system.' Thus, if a homogeneous cylinder be stood vertically upon either end, the line of gravity will coincide with the axis of the cylinder; but if the cylinder be then laid upon its side, the line of gravity will intersect the axis at right angles and will bisect it. Hence, in the cylinder, the center of gravity is at the center of the axis.

126. About the center of gravity the moments of all the forces of gravity are in equilibrium, in whatever position the body or system may be Hence, the body, or system, if suspended by this point, and acted upon by gravity alone, will balance itself; *i. e.*, if at rest it will remain at rest; or, if set in motion revolving about its center of gravity, and then left to itself, it will continue to revolve about that center indefinitely and with uniform angular velocity. Or, if suspended freely from any point, it will oscillate until the center of gravity comes to rest vertically under such point.

---

* Figs. 1 to 45, relating to Center of Gravity, are numbered independently of the rest of the series of figures relating to Statics.

127. In some bodies, such as the cube, or other parallelopiped, the sphere, etc., the center of *gravity* is also the center of the *weight* of the body; but very frequently this is not the case. Thus, in a body *a b*, Fig. 2, with its center of gravity at G, there is more weight on the side *a* G, than on the side G *b*.

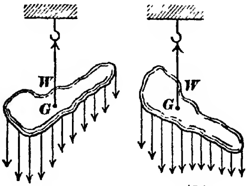

Fig. 1.

Stable, Unstable, and Indifferent Equilibrium.

128. A body is said to be in stable equilibrium when, as in the pendulum, it is so suspended that, if swung a little to either side, it tends to oscillate until it comes to rest again, with its center of gravity vertically under the point of suspension.

129. It is said to be in unstable equilibrium when, as in the case of an egg, stood upon its point, it is so supported that, if swung a little to either side, and left to itself, it swings farther out from the vertical and eventually falls

130. It is said to be in indifferent equilibrium when, as in the case of a grindstone, supported by its horizontal axis, or of a sphere resting upon a horizontal table, it is so suspended or supported that, if made to rotate about its center of gravity and then left to itself, it will continue in that state of rest or of angular motion in which it is left.

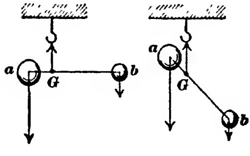

Fig. 2.

General Rules.

131. The following general rules (1) to (6), form the basis of the special rules, (7) to (39)

In speaking of the center of gravity of one or more **bodies**, we shall assume, for simplicity, that they are *homogeneous* (*i. e.*, of uniform density throughout) and of the same density with each other. The center of *gravity* is then the same as the center of *volume*, and we may use the *volumes* of the bodies (as in *cubic feet*, etc.) in the rules, instead of their *weights* (as in *pounds*, etc).

In applying these general rules to **surfaces**, use the *areas* of the surfaces, and in applying them to **lines**, use the *lengths* of the lines, in place of the weights or volumes of the bodies.

In all of the rules and figures, pp. 388 to 398, **G represents** the center of gravity, except where otherwise stated.

(1). Any two bodies, Fig. 3. Having found the center of gravity, g, g', of each body, by means of the rules given below: then **G** is in the line joining g and g'; and

$$g\,\mathbf{G} = g g' \times \frac{\text{weight of } g'}{\text{sum of weights of } g \text{ and } g'}$$

$$g'\,\mathbf{G} = g g' \times \frac{\text{weight of } g}{\text{sum of weights of } g \text{ and } g'}$$

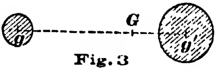

Fig. 3

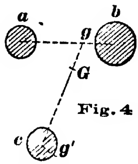

Fig. 4

(2). Any number of bodies, as a, b and c, Fig. 4, whether their **centers** of gravity are in the same plane or not.

First, by means of rule (1) find the center of gravity, g, of any two of the bodies, as a and b. Then the center of gravity, **G,** of the three bodies, a, b and c, is in the line $g g'$ joining g with the center of gravity, g' of c; and

$$g\,\mathbf{G} = g g' \times \frac{\text{weight of } c}{\text{sum of weights of } a,\, b \text{ and } c};$$

$$g'\,\mathbf{G} = g g' \times \frac{\text{sum of weights of } a \text{ and } b}{\text{sum of weights of } a,\, b \text{ and } c};$$

and so on, if there are other bodies.

(3). In many cases, **a single complex body** may be supposed to be divided into parts whose several centers of gravity can be readily found. Then the center of gravity of the whole may be found by the foregoing and following rules. Thus, in Fig. 5, we may find separately the centers of gravity of the

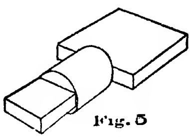

Fig. 5

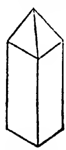

Fig. 6

two parallelopipeds and of the cylinder between them (each in the center of its respective portion of the whole solid); and in Fig. 6 the centers of gravity of the square prism and the square pyramid (the latter by rule (36), and then, knowing in either case the weights of the several parts, find their common center of gravity as directed in rules (1) and (2).

(4). **Any hollow body,** or body containing one or more openings, Fig. 7 Find the common center of gravity, g', of the openings by rule (1) or (2), and

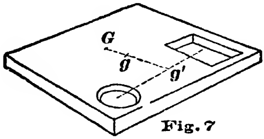

Fig. 7

the center of gravity, g, of the entire figure, as though it had no openings. Then G is in the line $g\,g'$, extended, and

$$g\,G = g\,g' \times \frac{\text{sum of volumes of openings}}{\text{volume of entire body} - \text{volumes of openings}}$$

$$g'\,G = g\,g' \times \frac{\text{volume of entire body}}{\text{volume of entire body} - \text{volumes of openings}}$$

REMARK. For convenience, we have shown the several centers of gravity, g, g', G, upon the *surface* of the figure. In the real solid (supposed to be of uniform thickness) they would of course be in the middle of its thickness and immediately under the positions shown in the figure.

(5). In any line, figure or body, or in any system of lines, figures or bodies, any plane passing through the center of gravity is called a **"plane of gravity"** for said line, etc., or system of lines, etc. The intersection of two such planes of gravity is called a **"line of gravity."** The center of gravity is (1st) the intersection of two lines of gravity; (2nd) the intersection of three planes of gravity, or (3rd) the intersection of a plane of gravity with a line of gravity not lying in said plane.

If a figure or body has an axis or plane of **symmetry** (*i. e.*, a line or plane dividing it into two equal and similar portions) said axis or plane is a line or plane of gravity. If a figure or body has a central point, said point is the center of gravity.

In Fig. 1, the string represents a line of gravity; and any plane with which the string coincides is a plane of gravity. Thus G may often be conveniently found, especially in the case of a flat body, by allowing it to hang freely from a string attached alternately at different corners of it, or by balancing it in two or more positions over a knife-edge, etc., and finding G in either case by the intersection of the lines or planes of gravity thus found.

(6). **The graphic method** of finding the resultant of parallel forces may often be advantageously used for finding the center of gravity of a compound body or figure, or of a system of bodies or figures, when the centers of gravity of the several parts are known.

Thus, in Fig. 8, let a, b and c represent three figures or bodies whose centers of gravity are in one plane. Draw vertical lines through said centers, and construct the polygon of forces, $x\,a\,b\,c$, Fig. 9, making the lines $x\,a$, $a\,b$, etc., proportional to the weights of a, b and c; and from any convenient point O draw radial lines O x, O a, etc. In Fig. 8, draw $m\,h$, $m\,n$, $n\,p$, and $p\,k$, parallel respectively to O x, O a, O b, O c. Then a vertical line, i G, drawn through the intersection, i, of $m\,h$ and $p\,k$, is a line of gravity of the system or figure. If the body or figure is *symmetrical*, as in the cross section of a T rail, I beam or deck beam, etc., the axis of symmetry, dividing the figure, etc. into two similar and equal parts, is also a line of gravity, and its intersection with the line i G already found is the required center of gravity G. In such cases it is generally most convenient to draw the lines through the several centers of gravity *perpendicular* to the axis of symmetry, so that the line of gravity found will also be perpendicular to it.

But if, as in Fig. 8, the body or figure, etc., is not symmetrical, we must find a second line of gravity, the intersection of which with the first will give the center of gravity, G. To do this, repeat the process, drawing another set of parallel lines through the several centers of gravity, Fig. 8. It will be most convenient to draw them horizontally, or *at right angles* to those already drawn, and in the following instructions we suppose this to be done.

Then draw a second funicular polygon, $m'\,n'\,p'\,i'$, Fig. 8, making the lines $m'\,n'$, etc., *perpendicular* (instead of parallel) to the radial lines O x, etc., Fig. 9; and draw the second line of gravity, i' G, through i', perpendicular to the first. Then G is at the intersection of the two lines of gravity.

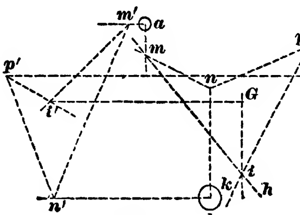

Fig. 8

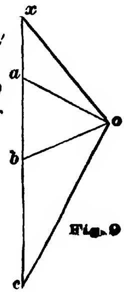

Fig. 9

The drawing of the second funicular polygon is often less simple than that of the first, because in the second the parallel lines through the several centers of gravity do not necessarily follow each other in the same order as in the first. Bear in mind that the two lines (as $n'\,p'$, $n'\,m'$) meeting in the parallel line (as $b\,n'$) pertaining to any given part, b, of the figure, must be perpendicular respectively to those radial lines (O a, O b) which meet the ends of the line, $a\,b$, that represents that same part.

Figs. 10 and 11 show the application of the same process to an irregular figure composed of three rectangles, a, b and c. The lettering is the same as in Figs. 8 and 9; but in Fig. 10 it happens that i' and p' of the second funicular polygon fall upon the same point.

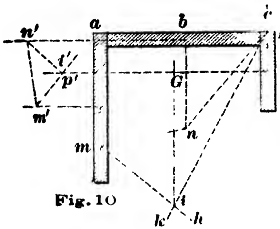

Fig. 10

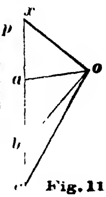

Fig. 11

If the centers of gravity of the several bodies, or of the several parts of the body, etc., are in more than one plane, we must find their projections upon certain planes, and apply the process to those projections.

Special Rules.

132. Special Rules, derived from the general rules, (1) to (6).

Lines.

(7). Straight line. **G** is in the line, and at the middle of its length.

(8). Circular arc,* $a\,o\,b$, Figs. 12 and 13 (center of circle at c). **G** is in the line $c\,o$ joining the center of the circle with the middle of the arc, and

$$c\,G = \text{radius } a\,c \times \frac{\text{chord } a\,b}{\text{length of arc } a\,o\,b}.$$

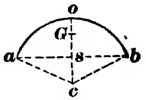

Fig. 12

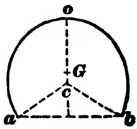

Fig. 13

(8a). If the arc is a semi-circle,*

$$c\,G = \text{radius } a\,c \times \frac{2}{\pi} = \text{radius } a\,c \times 0.6366.$$

(8b). Approximate rules for distance $s\,G$, Fig. 12, from *chord* to center of gravity.

If rise $s\,o$ = .01 chord $a\,b$;	$s\,G$ = .666 $s\,o$	If rise $s\,o$ = .30 chord $a\,b$;	$s\,G$ = .653 $s\,o$
" " " = .10 " " ;	" = .665 $s\,o$	" " " = .35 " " ;	" = .649 $s\,o$
" " " = .15 " " ;	" = .663 $s\,o$	" " " = .40 " " ;	" = .645 $s\,o$
" " " = .20 " " ;	" = .660 $s\,o$	" " " = .45 " " ;	" = .641 $s\,o$
" " " = .25 " " ;	" = .657 $s\,o$	" " " = .50 " " ;	" = .637 $s\,o$

(9). Triangle, $a\,b\,c$, Fig. 14. The center of gravity, **G**, of its three sides* is the center of the circle inscribed by a triangle, $d\,e\,f$, whose corners are in the centers of the sides of the given triangle.

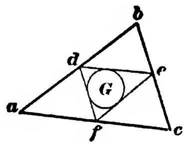

Fig. 14

(10). Parallelogram (square, rectangle, rhombus or rhomboid). The center of gravity of the four sides* is at the intersection of the diagonals.

(11). Circle, ellipse, or regular polygon. The center of gravity of the outline or circumference* is the center of the figure.

(12). Regular prism, right or oblique, and **right regular pyramid, or frustum.** The center of gravity of the edges* is the center of the axis. In the *prism*, the position of G is not affected by either including or excluding the sides of *both* of the polygons forming the ends.

(12a). Cycloid.* See p. 194.

Surfaces.

A. Plane surfaces.

We now treat of the centers of gravity of plane *surfaces*, which may be regarded as infinitely thin flat bodies. The rules for surfaces may be used also for actual flat bodies, in which, however, the center of gravity is in the middle of the thickness, immediately under the points found by the rules.

(13) Parallelogram (square, rectangle, rhombus or rhomboid), **circle, ellipse** or **regular polygon.** **G** is the center of the figure; or the intersection of any two diameters, or the middle of any diameter. In a **Parallelogram, G** is the intersection of the two diagonals.

(14). Triangle, Fig. 15. **G** is at the intersection of lines (as $a\,e$ and $c\,d$ drawn from any two angles, a and c, to the centers, e and d, of the sides, b

* We are now treating of *lines* only; not of the surfaces bounded by them. For surfaces, see rules (13), etc., etc.

and ab, respectively opposite to said angles. Such lines are called "medial lines."
$e\,\mathbf{G} = \frac{1}{3}\,a\,e;\quad d\,\mathbf{G} = \frac{1}{3}\,c\,d;\quad f\,\mathbf{G} = \frac{1}{3}\,b\,f$ (f being the middle of $a\,c$).

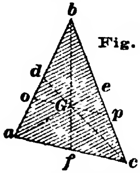

Fig. 15

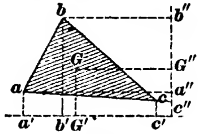

Fig. 16

(**14a**). Fig. 15. Or, on either one of the sides (as $a\,b$), meeting at any angle, a, make $a\,o = \frac{1}{3}\,ab$. Draw $o\,p$ parallel to the other side, $a\,c$. Then $o\,\mathbf{G} = \frac{1}{2}\,o\,p$, and $\mathbf{G}$ is at the intersection of $o\,p$ with any medial line, as $a\,e$, etc.

(**14b**). Fig. 16. If aa', bb', cc' and GG' are the distances of the three corners and of $\mathbf{G}$ from any straight line or plane $a'c'$; then

$$\mathbf{G}\,G' = \tfrac{1}{3}\,(a\,a' + b\,b' + c\,c').$$

This gives us the position of the line of gravity G G″. In the same way we find the distance G G″ of G from any second line or plane, $b''\,c''$ This gives us the position of a second line of gravity G G′. $\mathbf{G}$ is at the intersection of G G′ and G G″.

(**14c**). Fig. 17. The distance $\mathbf{G}\,n$ of $\mathbf{G}$ in any direction from any side, as $a\,c$ (extended if necessary) is $= \frac{1}{3}$ the distance $n'\,b$ measured in a parallel direction from the same side to the opposite angle, b.

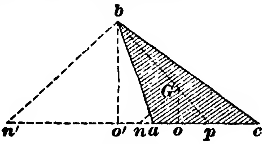

Fig. 17

It follows from this that the *shortest* distance, $\mathbf{G}\,o$, of $\mathbf{G}$ from any side (as $a\,c$) is $= \frac{1}{3}$ the shortest distance, $o'\,b$, from the same side to its opposite angle b. It follows also that $p\,G = \frac{1}{3}\,p\,b$, as in Rule (14)

(**15**). **Trapezium or trapezoid,** Fig. 18. For trapezoids, see also Rule (16). Draw the two diagonals, $a\,c$ and $b\,d$. Divide either of them, as $a\,c$, into two equal parts, $a\,m$ and $c\,m$. From b, on $b\,d$, lay off $b\,n = d\,s$ (or from d lay off $d\,n = b\,s$). Join $m\,n$. $\mathbf{G}$ is in $m\,n$, and

$$m\,\mathbf{G} = \tfrac{1}{3}\,m\,n.$$

($\mathbf{G}$ is the center of gravity of the triangle $a\,c\,n$).

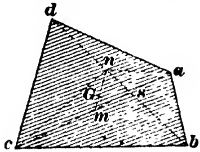

Fig. 18

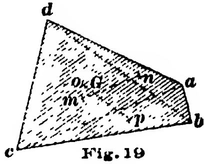

Fig. 19

(**15a**). Or, Fig. 19, find first the centers of gravity, m and n, of the two triangles, $c\,b\,d$ and $a\,b\,d$, into which the trapezium is divided by one of its diagonals, $b\,d$. Join $m\,n$ Then find the centers of gravity, o and p, of the two triangles, $d\,a\,c$ and $b\,a\,c$, into which the trapezium is divided by its *other* diagonal, $a\,c$. Join $o\,p$. Then $\mathbf{G}$ is the intersection of $m\,n$ and $o\,p$.

(**16**). **Trapezoid only,** Fig 20. **G** is in the line $e\,f$ joining the centers, e and f, of the two parallel sides, $a\,b$ and $c\,d$. To find its position in said line, prolong either parallel side, as $a\,b$, in either direction, say toward i; and make $b\,i$ equal to the opposite side, $c\,d$. Then prolong said opposite side, $c\,d$, in the opposite direction, making $d\,h = a\,b$. Join $h\,i$. Then **G** is the intersection of $h\,i$ and $e\,f$. Or

$$f\,G = \frac{e\,f}{3} \times \frac{2\,a\,b + c\,d}{a\,b + c\,d}; \quad \text{or } o\,G = \frac{e\,n}{3} \times \frac{2\,a\,b + c\,d}{a\,b + c\,d}$$

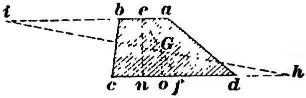

Fig. 20

(**17**). **Regular polygon.** **G** is the center of the figure.

(**17a**). **Irregular polygon.** If the polygon be divided into any two portions, as by any diagonal, **G** must be in the line (of gravity) joining the centers of gravity of those two portions. If we again divide the whole polygon into two *other* parts by *another* diagonal, and join the centers of gravity of those two parts, **G** is the intersection of the two lines of gravity.

(**17b**). Or we may divide the polygon into triangles, find the center of gravity of each triangle, by Rules (14), etc., and then find **G** by general Rule (1), (2) or (6).

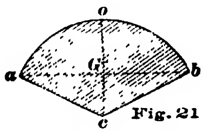

Fig. 21

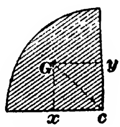

Fig. 22

(**18**). **Circular sector,** $a\,o\,b\,c$, **Fig.** 21. (Center of circle at c).

$$c\,G = \frac{2}{3}\ \text{radius}\ a\,c \times \frac{\text{chord}\ a\,b}{\text{arc}\ a\,o\,b} = \frac{\text{radius}^2 \times \text{chord}}{3 \times \text{area}}$$

For length of arc, see pp 179, etc.

(**18a**). If the sector is a **sextant,**

$$c\,G = \text{radius} \times \frac{2}{\pi} = \text{radius} \times 0.6366.$$

(**18b**). If the sector is a **quadrant,** Fig. 22,

$$c\,G = \frac{4}{3}\,\text{radius} \times \frac{\sqrt{2}}{\pi} = \text{radius} \times 0.6002.$$

$$c\,x = x\,G = \frac{4}{3}\ \text{radius} \times \frac{1}{\pi}.$$

(**18c**). If the sector is a **semi-circle,**

$$c\,G = \frac{4}{3}\ \text{radius} \times \frac{1}{\pi} = \text{radius} \times 0.4244.$$

$$= \text{(approximately) radius} \times \frac{14}{33}.$$

(19). **Circular segment,** $a\,o\,b\,s$, Fig. 23. (Center of circle at c).

$$c\,G = \frac{\text{cube of chord } a\,b}{12 \times \text{area of segment}}.$$

(19 a). If the segment is a **semi-circle,**

$$c\,G = \frac{4}{3}\,\text{radius} \times \frac{1}{\pi} = \text{radius} \times 0.4244$$

$$= \text{(approximately) radius} \times \frac{14}{33}.$$

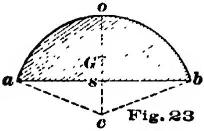

Fig. 23

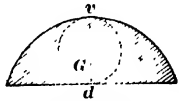

Fig. 24

(20). **Cycloid,** Fig. 24. (Vertex at v).

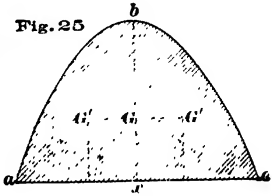
$$v\,G = \frac{7}{12}\,v\,d.$$

(21). **Parabola,** $a\,b\,c$, Fig. 25. $a\,c$ is the base; $a\,x$ and $c\,x$, ordinates; and the height or axis, $b\,x$, an abscissa. Center of gravity at **G,** in the axis $x\,b$, and

$$x\,G = \frac{2}{5}\,x\,b.$$

(21 a). **Semi-parabola,** $a\,b\,x$ or $c\,b\,x$. Center of gravity at G′, and

Fig. 25



$$x\,G = \frac{2}{5}\,x\,b; \qquad G\,G' = \frac{3}{8}\,a\,x = \frac{3}{8}\,c\,x.$$

(22). **Ellipse,** $m\,n\,o\,p$, Fig. 26. The center of gravity, c, of the **whole** ellipse is at the center of the figure.

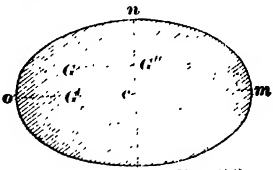


Fig. 26

G is the center of gravity of the quarter ellipse, $o\,n\,c$.
G′ " " " " " half " $n\,o\,p$.
G″ " " " " " " " $m\,n\,o$.

$$c\,G' = \frac{4}{3}\,o\,c \times \frac{1}{\pi} = 0.4244\,o\,c = \text{(approximately)}\ \frac{14}{33}\,o\,c.$$

$$c\,G'' = G'\,G = \frac{4}{3}\,c\,n \times \frac{1}{\pi} = 0.4244\,c\,n = \text{(approximately)}\ \frac{14}{33}\,c\,n.$$

(23). **Any plane figure.** Draw the figure to scale on stout card-board. Cut it out and balance it in two or more positions over the edge of a table or on a knife-edge; and mark on it the several positions of the supporting edge. Where these intersect is the center of gravity. Considerable care is of course necessary to obtain very close results by this method. Before balancing the card, its upper edges should be marked off into small equal spaces. Otherwise it will be difficult to locate the positions of the supporting edge. The paper on which the figure is prepared must of course be so stiff that the figure will not bend when balanced on the knife-edge. See Rule (5).

B. Surfaces of Solids.*

(24). Curved surface* of **sphere** or **spheroid (ellipsoid).** G is the center of the figure.

(25). Curved surface* of any **spherical zone,** as a **spherical segment, hemisphere,** etc., Figs. 27. G is the center of the axis or height, *a o*.†

In the **hemisphere,** $o\,G = \frac{1}{2}$ radius.†

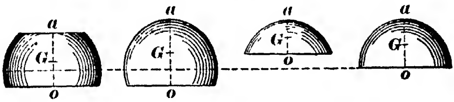

Fig. 27

(26). Right or oblique **prism,** whose ends are either regular figures or parallelograms (this includes the **cube** and other **parallelopipeds**); and right or oblique **cylinder** (circular or elliptic). *Surface** (either including both or excluding both of the two parallel ends). G is the center of the **axis,** or line joining the centers of the two parallel ends.

(27). Curved surface*† of right **cone,** Fig. 28 (circular or elliptic), or slanting surfaces*† of right regular **pyramid,** Fig. 29. G is in the **axis** *o a* (the line joining the apex and the center of the base); and

$$o\,G = \frac{1}{3}\,o\,a.$$

In an *oblique* cone or pyramid, the perpendicular distance of G* from the base is one-third of the perpendicular height, as in the right cone and pyramid; *but does not lie in the axis.*

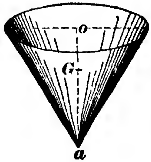

Fig. 28

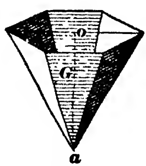

Fig. 29

(28). **Frustums** with top and base parallel, Figs 30 and 31. Curved surface*† of frustum of right cone (circular or elliptic); or slanting surfaces*† of frustum of right regular pyramid. G is in the **axis** *o a* (the line joining the centers of the two parallel ends); and

$$o\,G = \frac{1}{3}\,o\,a \times \frac{\text{circumference of } o + 2\,\text{circumference of } a.}{\text{circumference of } o + \text{circumference of } a.}$$

*We treat now of the *surfaces* of solids, not of their contents or volumes or weights. For these, see Rules (29), etc.

†If the **top** or **base** is to be included, see Rules (1) and (2).

In the **conic frustum,** Fig. 30, we may use the *radii* of the two ends; **and** in the **frustum of a regular pyramid,** Fig. 31, any *side* of each end (**as** bc and de) instead of the circumferences.

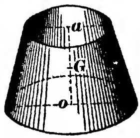

Fig. 30

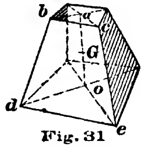

Fig. 31

Solids.

In the following rules for center of gravity of solids, the solid is supposed to be *homogeneous*; *i. e.*, of uniform density throughout; so that the center of *gravity* is the center of *magnitude* or of *volume*.

(29). Sphere and **spheroid (ellipsoid).** G is the center of the body.

(30). Hemisphere, Fig. 32. (Center of sphere at c). Height cT = radius cb. G is in the axis, cT, and

$$c\mathrm{G} = \frac{3}{8}\,c\mathrm{T} = \frac{3}{8}\text{ radius } cb.$$

(31). Spherical sector, Fig. 33. (Center of sphere at c).

$$c\mathrm{G} = \frac{3}{4}\left(\text{radius } cb - \frac{h}{2}\right).$$

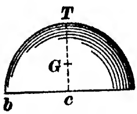

Fig. 32

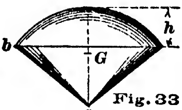

Fig. 33

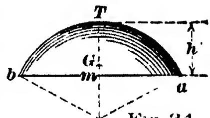

Fig. 34

(32). Spherical segment, ambT, Fig. 34. Center of *sphere* at c. Center of *base* at m. Rise or height of segment = mT = h. G is in the axis mT; and

$$c\mathrm{G} = \frac{3}{4} \times \frac{(2\text{ radius } cb\text{ of } sphere - \text{height } h)^2}{3\text{ radius } cb\text{ of } sphere - \text{height } h}$$

$$m\mathrm{G} = \frac{\text{height}, h}{2} \times \frac{2\,(\text{radius } mb\text{ of } base)^2 + (\text{height}, h)^2}{3\,(\text{radius } mb\text{ of } base)^2 + (\text{height}, h)^2}$$

$$= \frac{\text{height}, h}{4} \times \frac{4 \times \text{radius } cb\text{ of } sphere - \text{height}, h}{3 \times \text{radius } cb\text{ of } sphere - \text{height}, h}.$$

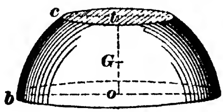

Fig. 35

(33). Spherical zone, Fig. 35.

$$o\mathrm{G} = \frac{ot}{2} \times \frac{2\,(\text{radius } ob\text{ of base})^2 + 4\,(\text{radius } tc\text{ of top})^2 + (\text{height } ot)^2}{3\,(\text{radius } ob\text{ of base})^2 + 3\,(\text{radius } tc\text{ of top})^2 + (\text{height } ot)^2}.$$

(34). Prism, regular or irregular, right or oblique (including the **cube** and other **parallelopipeds**), and **cylinder,** circular or elliptic, etc., regular or irregular, right or oblique. G is the center of the **axis** joining the **centers of gravity** of the two ends.

(34 *a*). A flat body, such as an iron plate, etc, may be treated as a very short cylinder or prism. See (34)

(35). Ungula of a cylinder, circular, or elliptic (provided one of the axes of the ellipse coincides with the oblique cutting plane); right or oblique. Figs. 36 and 37.

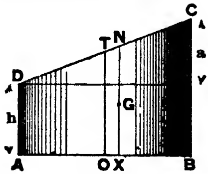

Fig. 36

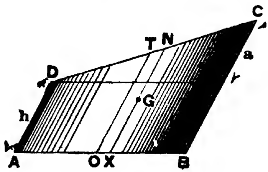

Fig. 37

Let O T be the axis (joining the centers of gravity of the ends), and X N a line drawn parallel to the axis, in the plane, A B C D, passing through the axis and through the uppermost and lowermost points C and D of the oblique cutting plane. Then the position of G in the plane A B C D, is found thus:

$$OX = \frac{OB}{4} \times \frac{a}{2h + a};$$

$$XG = \frac{XN}{2} = \frac{1}{4}\left(2h + a + \frac{1}{4}\,\frac{a^2}{2h + a}\right).$$

(35 *a*), Figs 38 and 39. If the oblique plane C D *meets* the base, A B, at A, so that $h = 0$, while C D remains a complete ellipse or circle, this becomes

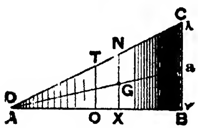

Fig. 38

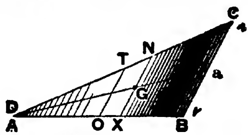

Fig. 39

$$OX = \frac{OB}{4};$$

$$XG = \frac{XN}{2} = \frac{5}{16}a$$

(36). Cone, Figs. 40 and 41, circular, elliptic, etc., right or oblique; or **pyramid,** regular or irregular, right or oblique. The center of gravity G is in the axis O T, drawn from the apex, or top, T, to the center of gravity O of the base; and

$$OG = \frac{OT}{4}.$$

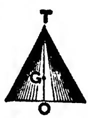

Fig. 40

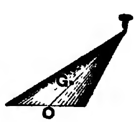

Fig. 41

(37). Frustum of a cone, Figs. 42 and 43, circular or elliptic, right or oblique; or **of a pyramid,** regular or irregular, right or oblique; provided the two ends A B and C D are parallel.

Call the area of the large end A, and that of the small end *a*; and let *h* be the height O Z of the frustum, *measured along its axis.* Then

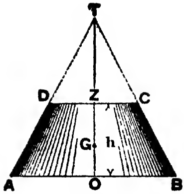

Fig. 42

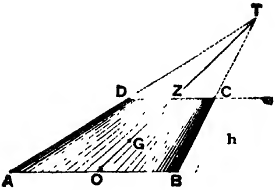

Fig. 43

G is in the axis O Z, which joins the centers of gravity O and Z of the two ends; and its distance from the base, A B, *measured along the axis*, is

$$O\,G = \frac{h}{4} \times \frac{A + 2\sqrt{A\,a} + 3\,a}{A + \sqrt{A\,a} + a}.$$

(37*a*). **In a frustum of a circular cone,** right or oblique, with **parallel ends,** this becomes

$$O\,G = \frac{h}{4} \times \frac{R^2 + 2\,R\,r + 3\,r^2}{R^2 + R\,r + r^2},$$

where R and *r* are the radii of the large and small ends of the frustum respectively.

(38). Figs. 44 and 45. **Frustum,** A B C D, **of a cone,** circular, elliptic etc., right or oblique; or **of a pyramid,** regular or irregular, right or oblique; whether the ends are parallel or not. By rule (36) find the center of gravity N of the *entire* pyramid (or cone, as the case may be) A B T, of which the frustum forms the lower part; and the center of gravity S of the smaller pyramid or cone D C T (= entire pyramid or cone, minus the frustum). Also find the *volume* of each: thus,

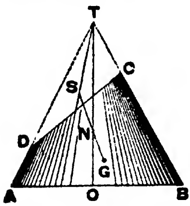

Fig. 44

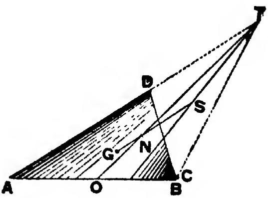

Fig. 45

$$\text{Volume of pyramid or cone} = \frac{\text{area of base} \times \text{perpendicular height}}{3},$$

and

Volume of the frustum A B C D	=	volume of entire pyramid or cone, A B T	−	volume of smaller one, D C T

Then the center of gravity G of the frustum A B C D is in the extension of the line S N; and

$$N\,G = S\,N \times \frac{\text{volume of smaller pyramid or cone, D C T}}{\text{volume of frustum, A B C D}}.$$

(39). **Paraboloid.** G is in the axis, and at one-third of its length from the base

LINE OF PRESSURE.
CENTER OF FORCE OR OF PRESSURE.

Position of Resultant.

133. In ¶¶ 133 to 154 we discuss the position of the resultant, or line of pressure, of a system of parallel forces acting against a surface. For the changes in that position within a structure, due to the action of non-parallel forces, see Arches, Dams, etc., ¶¶ 251, etc.

134. In a system of parallel forces, acting against a surface, the line of pressure, or pressure line, is the position of the resultant of the forces; and the center of force or center of pressure is the point where the pressure line meets that surface against which the forces act.

135. If the lengths of the lines which represent the forces be taken as representing weights, to scale, then the position of the pressure line is the line of gravity (see (5), ¶ 131) corresponding to those weights.

136. Thus, in Fig. 55 (*a*), ¶ 117, if the three forces, *a*, *b* and *c*, be taken as weights, represented to scale by the arrows, *a*, *b* and *c*, respectively, then the resultant R of the three forces occupies the position of the line of gravity of the three weights.

137. Again, in a mass of sand, Fig 61,* with an irregular surface, we may

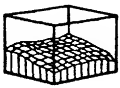

Fig. 61.

suppose the mass to consist of innumerable vertical columns of sand, of different heights, and exerting pressures proportional to those heights. Here, also, the pressure line is the vertical line of gravity of the mass, and the center of pressure against the base of the containing box is the point where said pressure line meets that base.

138. Although we are usually concerned with forces acting against *surfaces*, so that the lines representing the forces form a solid and not merely a surface, yet, in a majority of the cases which occur in civil engineering, we may, for convenience, regard the forces as concentrated in a single plane, and therefore as acting against a mere line.

139. Thus, in the case of an arch, pressing against its skewback, the pressure is ordinarily distributed over all or a considerable part of the bearing surface of the skewback; but we may, for convenience, regard it as concentrated in a single plane, midway between, and parallel to, the two faces of the arch.

140. Similarly, in the case of the water pressure against the back of a dam (or against a small strip of the back, extending from the water surface to the bottom, or to any other depth), the water, of course, presses upon the entire surface of such strip; but we may, for convenience, regard the pressure as concentrated in a vertical plane normal to the back of the dam and meeting it in the vertical axis of the assumed strip.

141. We have just seen (¶¶ 138 to 140) that, when a system of parallel pressures acts against a surface, they may often be assumed to act, in one plane, against a single line—viz., the intersection of that plane with the surface. It also frequently happens that such forces are so distributed along that line that the lines representing the forces are either of equal length or of lengths increasing uniformly from one end of the line to the other.

---

*Following Fig. 60, of Parallel Forces, ¶ 124. Figs. 1 to 45, illustrating Center of Gravity, are numbered independently of the rest of the series of figures relating to Statics.

142. Thus, in the case of water resting upon a horizontal surface, Fig. 62, *the pressure is uniformly distributed, and the diagram*, Fig. (*b*), representing the pressures, is a rectangle bounded by a horizontal line, and its center of gravity, G, is at the center of the figure. Hence, the center of pressure, *c*, is at the center of the line *a b*, or *l*.

Here the unit pressure, *p*, is uniform, and $R = p\,l$.

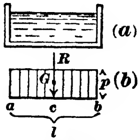

Fig. 62.

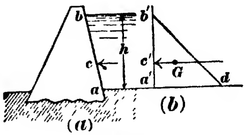

Fig. 63.

143. But when the water presses horizontally against a vertical or inclined surface, *a b*, Fig. 63, the unit pressure increases uniformly from zero, at the water surface, *b*, to a max at the bottom, *a*; and the hor pressures are represented, in Fig (*b*), by the ordinates of the triangle *b' a' d*. Since the resultant passes through the center of gravity, G, of the triangle, the center of pressure, *c*, is at such a depth that $c\,a = \frac{1}{3}\,a\,b$, and $c'\,a' = \frac{1}{3}\,h$. See Rule (**14** *c*) under Center of Gravity.

Here the mean horizontal unit pressure, *p*, is half the maximum horizontal pressure at *a*, and the total horizontal pressure is $= p\,h$.

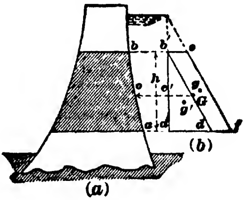

Fig. 64.

144. Again, if we consider only the water pressures against a certain *part*, *a b*, Fig. 64, of the depth of the back of a dam, the diagram, Fig. (*b*), representing the horizontal unit pressures, becomes a trapezoid, composed of a parallelogram *b' f*, and a triangle *b' a' d*, with their centers of gravity at *g* and *g'* respectively; and the center of pressure, *c*, on *a b*, is opposite their common center of gravity (center of gravity of trapezoid), G. If *h* be the vertical depth of the portion considered, then

$$a'\,c' = \frac{h}{3} \times \frac{2\,b'\,e + a'\,f}{b'\,e + a'\,f}.$$

See Rule (**16**) under Center of Gravity.* See also Center of Pressure, under Hydrostatics.

Distribution of Pressure.

145. Conversely, if two surfaces, as those of a masonry joint, are in such contact that the pressure is, or may be regarded as, regularly distributed, and if the position of the resultant is known, the rectilinear figure, representing the distribution of pressure, may be drawn by means of the principles just stated.

146. In Figs. 65 to 68 inclusive, let

o = the center of the joint $a\,b$ between the two surfaces;
R = the total pressure = resultant of all the pressures;
c = point of application of resultant, R;
l = $a\,b$ = the length of the joint;
x = $o\,c$ = the distance of the center of pressure from the center of the joint;
y = $\frac{l}{2} - x = a\,c$ = distance of center of pressure from nearest end of joint;
p = the mean unit pressure = $\frac{R}{l}$;
p_a = the maximum unit pressure;
p_b = the minimum unit pressure.

¶¶ 147 to 154 apply equally whether the surface is horizontal, vertical or inclined, and whether the forces are normal or inclined to it.

147. If x is not greater than $\frac{l}{6}$, or, in any case, if the joint is capable of sustaining tension, as well as compression, we have:

$$\text{Maximum unit pressure} = p_a = p\,(1 + \frac{6\,x}{l});$$

$$\text{Minimum unit pressure} = p_b = p\,(1 - \frac{6\,x}{l}).$$

If x exceeds $\frac{l}{6}$, and if the joint is incapable of resisting tension, see ¶¶ 151, 152, 154.

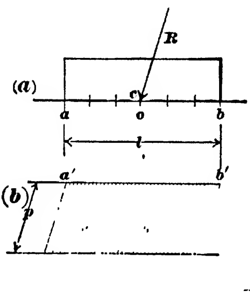

Fig. 65.

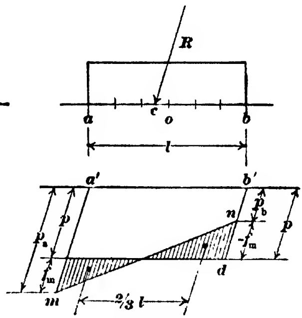

Fig. 66.

148. Demonstration. In Fig. 66, where the parallelogram $a'\,d$ represents the total pressure R as it would be if uniformly distributed along l, we see that the moment of R, about o, which changes the parallelogram $a'\,d$ into the trapezoid $a'\,b'\,n\,m$, is equivalent to a couple (see Couples, ¶ 155, etc) composed of two forces—viz., a pressure, f (not shown) distributed over $o\,a$ and represented by the shaded triangle on the left, and a tension, $-f$, or diminution of pressure, distributed over $o\,b$ and represented by the triangle on the right. The forces, f and $-f$, act through the centers of gravity of these two triangles respectively; and the distance of each of these centers of gravity from the center, o, of the joint, measured parallel to the joint, is $= \frac{2}{3} \cdot \frac{l}{2}$. Hence the distance between the two centers of gravity, meas-

ured parallel to the joint, is $= \frac{2l}{3}$. Let x be the eccentricity, $c\,o$, of R, measured along the joint, and let A_R and A_C (not shown) be the lever arms of R and of the couple, respectively, about the center, o, of the joint. Then, since R is parallel to f and $-f$, A_R to A_C, and x to l, we have:

$$A_R : A_C = x : \frac{2l}{3}.$$

If R is normal to the joint, we have: $A_R = x$; and $A_C = \frac{2l}{3}$.

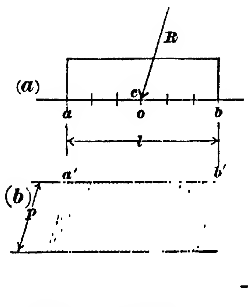

Fig. 65 (repeated).

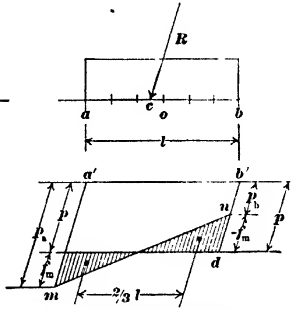

Fig. 66 (repeated).

$$\text{Now} \qquad f = \frac{\text{moment of R}}{\text{arm of couple}} = \frac{R\ A_R}{A_C}.$$

$$\text{Hence,} \qquad f = \frac{R\ x}{\frac{2l}{3}} = \frac{R}{l} \cdot \frac{3x}{2} = p\,\frac{3x}{2}.$$

The *mean* additional pressure on $o\,a$ (or mean tension on $o\,b$) is $= \frac{f}{\frac{1}{2}l}$ and the corresponding maximum additional pressure is

$$f_m = 2\,\frac{f}{\frac{1}{2}l} = \frac{4}{l}\,f = \frac{4}{l}\,p\,\frac{3x}{2} = p\,\frac{6x}{l}.$$

$$\text{Now } p_a = p + f_m = p + p\,\frac{6x}{l} = p\left(1 + \frac{6x}{l}\right)$$

$$\text{and } p_b = p - f_m = p - p\,\frac{6x}{l} = p\left(1 - \frac{6x}{l}\right).$$

149. If, as in Fig. 65, the center of pressure, c, is at the center, o, of the surface, we have $x = o\,c =$ zero, and the pressure, R, is uniformly distributed over the surface.

150. "The Middle Third." If, as in Fig 67, $x = \frac{l}{6}$, — i e, if the resultant, R, of all the forces, meets the surface at the edge of the middle third of that surface, then $p_a = 2\,p$; and $p_b = 0$ See ¶¶ 143 and 148.

151. When, as in Fig. 68 (a), x exceeds $\frac{l}{6}$, — i e, when the center of pressure, c, falls beyond the middle third of the surface of pressure, a portion, $s\,b$, of the surface, is in tension, the maximum tension, p_b, Fig. 68 (b), being $= p\left(1 - \frac{6x}{l}\right)$ as above; maximum pressure $= p\left(1 + \frac{6x}{l}\right)$, and total pressure on $a\,s = \frac{p_a \cdot a\,s}{2} =$ R *plus* the tension in $s\,b$; but if, as usually

happens in masonry, the surfaces are incapable of resisting tension, the total pressure, R, is simply concentrated upon a portion $a\,v$, Fig. 68 (a), of the surface, $a\,v$ being $= 3\,y$.

Then, mean unit pressure on $a\,v = \frac{R}{a\,v} = \frac{R}{3\,y}$;

$$p_a = 2\,\frac{R}{3\,y} = 2\,\frac{p\,l}{3\,y}.$$

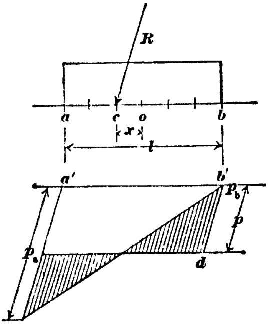

Fig. 67.

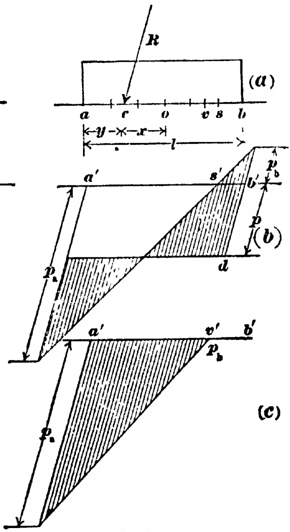

Fig. 68.

152. Hence, in a joint incapable of sustaining tension, Fig. 68 (c), if $p_a = 2\,\frac{R}{3\,y}$ is the maximum permissible unit stress, the distance $a\,c$, from the center of pressure, c, to the nearest end of the joint, must not be less than $y = \frac{2\,R}{3\,p_a}$.

153. If the joint can resist tension, Fig. 68 (b), we substitute, in the equation, $p_a = p\,(1 + \frac{6\,x}{l})$, the value of $x = \frac{l}{2} - y$, and, solving for y, we have

$$y = \frac{2}{3}\,l - \frac{p_a\,l}{6\,p}.$$

154. The influence diagrams, Fig. 69 (see ¶¶ 339, etc., and Trusses, ¶¶ 79, etc.), show the changes in the maximum and minimum unit pressures, p_a and p_b, as the center of pressure, c, recedes from the center, o, of the joint. The diagrams are constructed for a mean unit pressure, p, of 1. If the surfaces of the joint are capable of sustaining tension, every part of the joint always sustains either pressure or tension; and (see dotted lines,

Fig. 69) the maximum unit pressure, $p_a = p\,(1 + \frac{6\,x}{l})$, see ¶ 146, increases proportionally with x; becoming $= 4\,p = \frac{4\,R}{l}$ when c reaches the end, a, of the joint, and when $\frac{x}{l} = \frac{1}{2}$. The max tension, p_b, is then $= 2\,p = \frac{2\,R}{l}$. But if the surfaces are incapable of sustaining tension (see solid lines, Fig. 69), the increase of p_a is proportional to x only so long as $x < \frac{l}{6}$;—*i. e.*, so long as the resultant of all the pressures falls within the middle third of the base $a\,b$. When that limit is exceeded, the maximum unit pressure, p_a, begins to increase more rapidly than does the distance, x, of c, from the center, o, of the joint, the diagram becoming a rectangular hyperbola; so that, if the resultant could be actually applied at the very edge of the joint, the unit pressure there would become infinite.

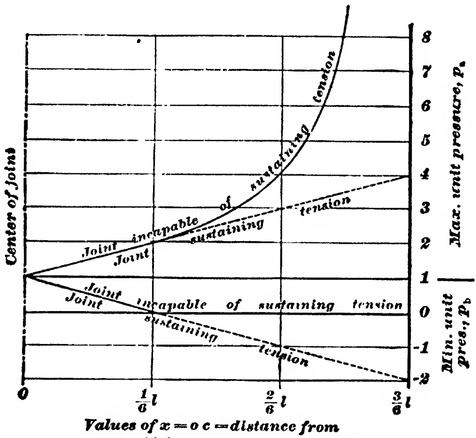

Fig. 69.

COUPLES.

155. Couples. Two equal parallel forces, p and q, or p' and q', Fig. 70,* of opposite sense, are called a couple. A couple has no tendency to move the body † as a whole in any straight line. In other words, the two forces, forming a couple, can have no resultant. Their only tendency is to make the body revolve about its center of gravity, G, and in the **plane of the couple**—*i. e.*, the plane in which the two forces lie. A body with a fixed axis can revolve only in a plane normal to that axis. The actual plane of rotation of a free body depends upon the distribution of mass in the body, and is not necessarily the plane of the couple.

---

* Figs. 70 to 75 are supposed to be seen in perspective, and the forces are supposed to act in the planes shown.

† See foot-note (*), ¶ 1.

156. The moment of a couple is equal to the product of one of the two forces, p or q, into the perpendicular distance, d, between the two forces. Or, in our figures,

$$\text{moment of couple} = p \cdot d = q \cdot d.$$

157. Graphic Representation of Couples. A couple, M or N, Fig. 70, is indicated, in amount, in direction and in sense, by a line, L or L', normal to the plane of the couple, so placed that, looking along it toward that plane, the couple appears positive or right-handed, and of such length as to represent, by scale, the moment of the couple. In Fig. 70, the two couples M and N are of opposite sense. Hence the lines L and L', representing them, project in opposite directions from their respective planes.

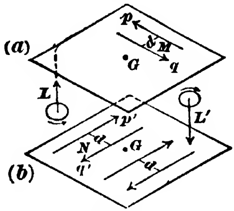

Fig. 70.

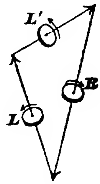

Fig. 71.

158. Composition of Couples. If the lines, L and L', Fig. 71, represent two couples, in accordance with ¶ 157, then the line R, completing the triangle, will, in the same way, represent their resultant or anti-resultant. As drawn, with its arrow *following* those of the other two sides, it represents their *anti*-resultant. For their resultant, the arrow on R, and that indicating the direction of rotation, must be reversed.

159. Equality of Couples. Two couples, M and N, in the same plane, Fig. 72 or Fig. 73, or in parallel planes, Fig. 70, are equal if their moments are equal, whether or not the forces of one of the couples be equal or parallel to those of the other. In Fig. 73, the two couples, M and N, are of like sense; in Figs. 70 and 72, of opposite sense.

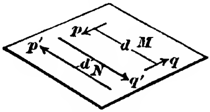

Fig. 72.

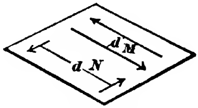

Fig. 73.

160. Since a couple has no resultant (¶ 155), it can have no anti-resultant; *i. e.*, no single force can balance a couple and thus preserve equilibrium. (But see ¶ 168.) To do this requires an equal and opposite couple. Thus, in Fig. 72 the couple M is balanced by the equal and opposite couple N. If, as in Fig. 72, the two couples are in the same plane, and if we find first the resultant of either pair of non-parallel forces, as p and p', and then those of the other pair, q and q', we shall find these resultants equal and opposite, maintaining equilibrium.

161. Any couple, as M, Fig. 73, **may be replaced** by any other equal couple, N, in the same plane or in a parallel plane, and of like sense.

162. If, to a force, P, Fig. 74 (a), **we add a couple,** M, Fig. 74 (b), in the same plane with the force, we may replace the couple, M, by an equal and like couple, N, Fig. (c), composed of the forces, —P and P', each = P, placing —P opposite P, as shown. Then P and —P counteract each other, and we have left only P', equal and parallel to P; and, since Pd = M, we have

$d = \frac{M}{p}$. In other words, the effect of the addition of the couple, M, Fig. (*b*), to the force, P, is simply to shift the line of action of P, parallel with itself, through the distance, *d*. If the couple M is left-handed, as in the figure, P will be shifted to the right (looking in its own direction), and vice versa.

163. Conversely, the force, P′, Fig. (*c*), is equivalent to the combination of force P and couple M, Fig. (*b*).

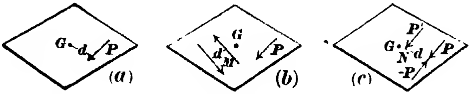

Fig. 74.

164. Again, having only the force P″, Fig. (*c*), if we apply, at a distance, *d*, from P′, the two opposite forces, P and —P, each equal and parallel to P″, we shall thus substitute, for P″, the equal and parallel force, P, and a couple = P*d* = M.

165. Hence, also, the combination of the force P and the couple M, Fig (*b*), is equivalent to the combination of the force P and the couple N, Fig. (*c*).

166. If the moment of the couple, M, Fig. (*b*), or N, Fig. (*c*), be equal and opposite to the moment of the force P about the center of gravity, G, of a body, we have $d = \frac{M}{P}$ = distance from P to G. In other words, the effect of such a couple is to shift the force, P, parallel with itself, to a line passing through the center of gravity, G.

167. Hence, the effect of a force, P, Fig. (*a*), applied to a body at a distance, *d*, from its center of gravity, G, is equivalent to the combined effect of an equal and parallel force, P′, Fig. (*c*), applied at the center of gravity, and a couple (as M, Fig *b*) = P*d*, and of like sense, applied to any part of the body in a plane parallel to P and P′.

168. It will be seen that, although (¶ 160) no single force can balance a couple and establish equilibrium, yet, if a force, P, be so applied that its moment, P*d*, about the center of gravity, G, of the body, is equal and opposite to the moment of the couple, it will counteract the tendency to rotation, due to the couple, and substitute for it a motion of translation only.

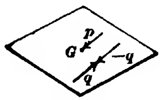

Fig. 75.

169. Thus, in Fig. 75, where the force, *p*, acts through the center of gravity, G, of the body, let a force, —*q*, equal and opposite to *q*, be applied in the same line with it. Then rotation will be prevented, and the body will move * under the action of *p* (= the resultant of the three forces), which acts through the center of gravity, G, of the body. The rotation will similarly be prevented if a force *less* than *q* be applied *farther* from G than *q* is; or if a force *greater* than *q* be applied *nearer* G than *q* is; provided always that the moment of said third force, about G, be equal and opposite to that of the couple *p q*. But in the first case the resultant of the three forces (being always equal to the third force) will be less, and in the second case greater, than *p*.

170. If, to a couple, be added a third force, colinear with one of the forces of the couple, we have the case of two unequal parallel forces of opposite sense. See ¶ 112, under Parallel Forces.

* See foot-note (*) ¶ 1.

170 a. Moments of Couples. The two equal and parallel forces, P and P', Fig A, in opposite directions, form a clockwise couple $= PL = P'L$, where L = the distance between the lines of action of the forces. Taking the moments of the forces about any point, as A, B, C or D, and considering *clockwise* moments as *positive*, we have

$$Pm - P'n = P(m - n) = P's - Pr = P(s - r)$$
$$= Pt + P'u = P(t + u) = P \times 0 + P'L = PL = P'L.$$

In other words, while the moments, Pm, Pr, etc, of the *forces* are *different* for different points, A, B, etc, the moment, $PL = P'L$, of the *couple* is the *same* for *all* points.

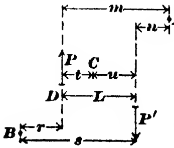

Fig. A.

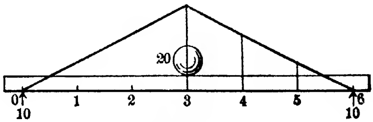

Fig. B.

Thus, suppose the beam, Fig B, to be divided by a vertical section at 4. The right segment is acted upon, at Section 4, by a downward force = load — left reaction = 20 — 10 = 10, and, at 6, by an upward force = right reaction = 10. These forces form a left-hand couple, with moment = 2 × 10 = 20. The left segment is acted upon, at 0, by the left reaction = 10; at 3, by the load = 20; and, at Section 4, by the right reaction = 10. Combining the two reactions, we find their resultant, = 10 + 10 = 20, at 2 (midway betw 0 and 4), forming, with the load, 20, a right-hand couple, with moment = 1 × 20 = 20.

At Section 5, by a similar process, we find couples with moments = 10, and, at Section 3, couples with moments = 30. Thus, altho the moment of a couple is the same, about whatever point moments be taken, yet, in a beam, under a given set of forces arranged in a given manner, the moment varies from point to point; because, in that case, the *couples* are different.

As the tendency to rotation, at any section, is thus seen to be caused by two equal and opposite couples, acting upon the two segments respectively; so the tendency to rotation is resisted by two equal and opposite couples, due to the internal stresses of the material, and acting, in the section, upon the two segments respectively

FRICTION.*

171. When one rough body rests upon another, the projections and depressions, forming **the roughnesses** of their surfaces of contact, **interlock** to a greater or less extent; and, in order to slide one over the other, we must expend a portion of the sliding force, either in *separating* the bodies (as by lifting the upper one) sufficiently to clear the projections, or in breaking off some of the projections and clearing the others.

172. Even the most highly polished flat surface, as *x y*, Fig. 76, is *not* (as it appears to the eye) a *plane*, but is, in fact, a more or less jagged surface, as would appear under a sufficiently powerful microscope; so that the force, *a b*, instead of forming the *apparent* angle, *a b x*, with *one* smooth surface, *x y*, of application, really becomes a series of parallel forces, as *c*, *d* and *e*, which form *other* angles with a number of surfaces, *m m*, *n n*, etc., of application, *inclined* (often in different directions) to the general surface, *x y*, as shown. Among these surfaces may be some, as *m m*, at right angles to the applied force; and, the force *c* will be imparted to them in its original direction, although applied *obliquely* to the *apparent* surface, *x y* In the case of the two forces, *d* and *e*, applied to the surfaces, *n n* and *s s*, if the sliding tendencies along the two surfaces are *equal* and act in *opposition* to each other, the *combined* resistance of the two surfaces, *n n* and *s s*, is directly opposite to the forces, as would be that of a single surface at right angles to those forces.

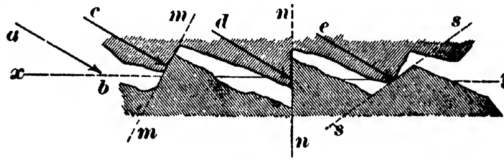

Fig. 76.

173. It is of course entirely out of the question to ascertain the exact resistance of each such microscopic projection in any given case. Instead of this, we find by experiment the *combined* resistance which *all* of the projections, in a given case, offer to the sliding force, and give to this resistance the name of **friction.**

174. Friction always tends to *prevent relative motion of the two bodies between which it acts; i e*, motion of one of the bodies relatively to the other. In doing so, however, it tends equally to *cause* relative motion † between each of those two and *a third, or outside body* Thus, the fric between a belt and the pulley *driven by it* tends to prevent slipping between *them;* but thus tends to make the belt slip on the *driving* pulley, and sets the *driven* pulley and its shaft in motion *relatively to the bearing* in which the shaft revolves. *This* motion is resisted by the fric *between journal and bearing*; and *this* fric, in turn, tends equally to make the *bearing* revolve with the journal, and to make the belt slip on the driven pulley.

175. The fric between two bodies *at rest* relatively to each other is called **static friction,** or fric of rest. That between two bodies *in relative motion* is called **kinetic friction** or fric of motion.

176. The ultimate or maximum static fric between two bodies, as U and L, Fig. 77 (or the greatest fric resistance which they are capable of opposing to any sliding force when at rest), is equal to a force (as that of

---

* "Friction" (meaning rubbing) is a misnomer in so far as it implies that rubbing must take place in order to produce the resistance. For we meet this resistance, not only during rubbing, but also before motion (or rubbing) takes place. "Resistance of roughness" would better express its nature.

† See foot-note (*), ¶ 1.

the wt F) which is just upon the point of making U begin to slide upon L.* Thus fric, like other forces, may be expressed in *weights*, as in lbs.

177. A resistce cannot exceed the force which it resists.† Therefore if F is less than the ult static fric between U and L, the *frictional resistce actually exerted* by them is also less. When F is = the ult fric (and U is therefore on the point of sliding) the actual resistce is = the ult stat fric. If F exceeds the ult stat fric, the excess gives motion to U.

178. If, when a body is in motion, all extraneous forces and resistces are removed or kept in equilib, it moves at a uniform vel. Hence, if the force, F, Fig. 77, is just = the ultimate kinetic fric between U and L, their vel is uniform. If F exceeds this, the excess *accelerates* the vel. If the ult kinetic fric exceeds F, the excess *retards* the vel. Thus **the actual frictional resistce** exerted by two bodies *in relative motion* is = their **ult kinetic fric** = that force (as F) which can just maintain their relative vel uniform.

179. Hence, if the hor surf S upon which L rests, could be made perfectly frictionless, the pres of L against the lug *m* (which would then always be = the *actual* fric resistce between U and L) would also be = their *ult* fric so long as U continued in motion over L, and might therefore be greater or less than or = F; but when U was at rest the pres against *m* would be = F, and less than (or at most just =) the ult fric.

Coefficient of Friction.

180. Since no surface can be made *absolutely* smooth, some separation of the two bodies must in all cases take place in order to clear such projections as exist. Hence the fric is always more or less affected by the amount of the perp pres which tends to keep them together.

181. The ratio of the ult fric, in a given case, to the perp pres, is called **the coefficient of friction** for that case. Or,

$$\text{Coefficient of friction} = \frac{\text{ultimate friction}}{\text{perpendicular pressure}}$$

and

$$\text{Ultimate friction} = \text{perp pres} \times \text{coeff of fric}$$

Thus, if a force F, Fig 77, of 10 lbs, just balances the ult fric between U and L, and if the wt of U (the perp pres in this case since the surf between U and L is *hor*) is 50 lbs, then the coeff of fric between U and L is $= \frac{10 \text{ lbs}}{50 \text{ lbs}}$ = 0.2.

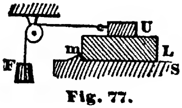

Fig. 77.

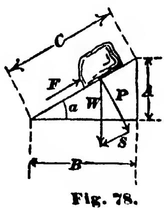

Fig. 78.

182. The coeff is usually expressed decimally, or by a common fraction; but sometimes, as in the case of railroad cars and engines, in lbs (of fric) per ton (of perp pres). Or by the "angle of fric" in degs and mins.

* We here neglect the fric of the string and pulley, and assume that *all* the force of the wt F is transmitted by the string to U.

† If a resisting *force* exceeds the force resisted, the excess is not resistce, but motive force

183. Angle of Friction. In Fig. 78, let W = the weight of the body; P = its pressure normal to the plane, and S = the component tending to slide the body down the plane.

When the angle a is such that the body is just on the point of sliding down the plane, it is called the angle of friction, or angle of repose. The friction F and the sliding force S are then equal.

But $\frac{S}{P} = \frac{F}{P} = \frac{A}{B}$ = coefficient of friction = tan a. Hence F = P tan a = W cosin a . tan a.

184. Frictional Stability. Let R, Fig. 79, be the resultant of all the forces pressing a body against a plane, and N a normal to the plane. If the angle i between R and N exceeds the angle of friction (a, Fig. 78) between the two surfaces in contact, the body will slide on the plane, but not otherwise. If i does not exceed the angle of friction, the entire resultant R will be imparted to the plane and in its own direction, and not merely its normal component V, as would be the case if the surfaces were frictionless.

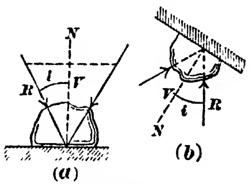

Fig. 79.

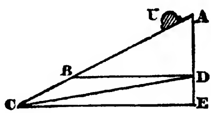

Fig. 80.

185. To find the coeff of kinetic fric, allow one of the bodies, U, Fig. 80, to slide down an inclined plane A C formed of the other one and having any convenient known steepness A C E greater than the angle of fric (¶ 183). Note the *vert* dist A E through which U descends in sliding any dist as A C (A E = A C × sine of A C E); also its actual *sliding* vel in ft per sec on reaching C. Calculate the *vert* dist A D through which it would have to descend *along the plane* (from A to B) to acquire that vel *if there were no fric.*

$$\left(\text{A D} = \frac{\text{velocity}^2 \text{ in ft per sec}}{\text{twice the accel } g \text{ of grav *}}\right).$$

Find D E (= A E — A D), and the hor dist E C corresponding to A C (E C = A C × cosine A C E = $\sqrt{\text{A C}^2 - \text{A E}^2}$). Then

$$\text{Coeff of the average fric in sliding from A to C} = \frac{\text{D E}}{\text{E C}},$$

because, if we let A E represent the *total* sliding force expended (in acceleration and in overcoming the fric), then A D represents the portion of A E expended on *vel*, and D E that expended on *fric*, and, since C E represents the perpendicular pressure (¶ 183),

$$\frac{\text{D E}}{\text{E C}} = \frac{\text{friction}}{\text{prep pres}} = \text{coeff.}$$

186. Or, find sine and tangent of A C E; and the dist A C (= time² in secs × ½ g * × sine of A C E) through which U *would* slide in a given time *if there were no fric.* Measure the dist A B through which it *actually slides* in that time; and find B C = A C — A B. Then

$$\left.\begin{array}{l}\text{coeff of the average}\\ \text{fric in sliding from A to B}\end{array}\right\} = \tan \text{D C E} = \tan \text{A C E} \times \frac{\text{B C}}{\text{A C}}$$

because

* g = about 32.2 ft per second per second.

(1st) A C : A B : B C :: A E : A D : D E

:: the theoretical velocity due to total sliding force : the actual velocity : the frictional retardation

:: the total sliding force : sliding force employed in giving the actual velocity : the friction, or the sliding force required to balance the friction.

And, if A E is = the total sliding force, then E C is = the perpendicular pressure, and

$$\frac{DE}{EC} = \text{the coefficient of friction} = \text{tangent of } DCE.$$

(2nd) Owing to the similarity of the two triangles, A B D and A C E, we have A C : B C :: A E : D E :: $\frac{AE}{EC} : \frac{DE}{EC}$ :: tangent A C E : tangent D C E.

187. In 1831 to 1834, **Gen'l Arthur Morin*** experimented with pressures not exceeding about 30 lbs per sq in; and arrived at the following conclusions in regard to sliding fric where the perp pres is considerably less than would be necessary to abrade the surfs appreciably. These were for a long time generally regarded as constituting the **three fundamental laws of fric.**

1st. The ult fric between two bodies is proportional to the total perp force which presses them together; *i e*, the **coeff is independent of the perp pres** and of its *intensity* (pres *per unit of surf*). Hence

2d. For any given *total* perp pres, **the coeff is independent of the area of surf in contact.**

If upon a hor support we lay a brick, measuring 8 × 4 × 2 ins, first upon its long edge (8 × 2 ins) and then upon its side (8 × 4 ins), we double the area of contact, while the total pres (the wt of the brick) remains the same, and *thus reduce the pres per sq in* by one-half. Consequently (the coeff remaining practically the same) we have only half the *fric per sq in*. But we have twice as many sq ins of contact, and therefore the same *total* fric.

But if we can increase or diminish the area of contact *without affecting the pres per sq in*, the *total* pres will of course *vary as the area*, and the total fric will vary in the same proportion, for the coeff remains the same Thus, if we place two similar sheets of paper between the leaves of a book (taking care not to place both sheets between the same two leaves) and then squeeze the book in a letter-copying press, it will require about twice as much force to pull out both sheets as to pull out only one of them.

3d. Although the coeff of *static* fric between two bodies is often much greater than their coeff of kinetic fric; yet **the coeff of kinetic fric is independent of the vel.**

This applies also (approx) to the *fric*, and hence to the *work* (in *foot*-pounds etc) of overcoming fric through a given *dist*; for then the work (= resistce × dist) is independent of the vel. But in a given *time*, the dist (and consequently the work also) of course varies as the vel.

188. **(a)** Some kinds of surfaces appear to interlock their projections much more perfectly when at rest relatively to each other, than when in even very slow motion; and in some cases the degree of interlocking seems to increase with time of contact. Hence there is often a great diff in amount between fric of rest and fric of motion. Thus, Gen'l Morin found that with oak upon oak, fibres of the two pieces at right angles, the resistce to sliding while still at rest, and after being for "some time in contact," was about one eighth greater than when the pieces had a relative vel of from 1 to 5 ft per sec.

(b) But experience shows that even very slight jarring suffices to remove this diff; and since all structures, even the heaviest, are subject to occasional jarring, (as a bridge, or a neighboring building, or even a hill, during the passage of a train; or a large factory by the motion of its machinery; or in numberless cases, by the action of the wind) it is expedient, in construction, not to rely on fric for *stability* any further than the coeff for *moving* fric will justify. When it is to be regarded as a resistce, which we must provide force for overcoming, it should be taken at considerably *more* than our tabular statement.

* See his "Fundamental Ideas of Mechanics", translated by Jos. Bennett; D. Appleton & Co., New York. 1860.

Table of moving friction, of perfectly smooth, clean, and dry, plane surfaces, chiefly from Morin.

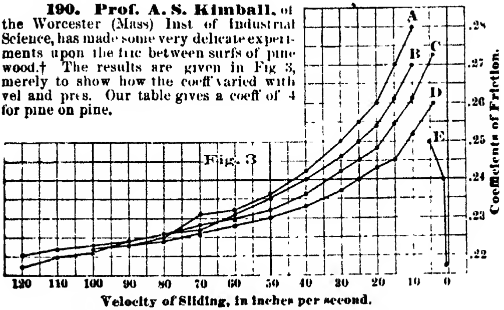
* But after a few trials the surfaces become so much smoother as to reduce the angles as much as 8 m 2° to 5°; the sliding blocks weighing about 30 lbs each.

189. Recent experiments, with much greater variations of pres and of vel, and with more delicate apparatus for detecting slight changes in the coeff, although giving conflicting results,* show that **the three laws** in ¶ 187 are far from correct for surfs moving at high vels, and under great pres; and that they **are only approximately correct** for ordinary vels and pressures; for the coeff is found to vary both with the intensity of the pres and with the vel, as also with the temperature.* But in the cases with which the civil engineer has mostly to deal, slight diffs in the character of the surfs, or even in the dampness of the air, will often cause much greater changes of coeff than those due to any probable changes of pres, vel and temp: so that, within the limits of abrasion, we may generally take Morin's rules as sufficiently correct for such cases.

190. Prof. A. S. Kimball, of the Worcester (Mass) Inst of Industrial Science, has made some very delicate experiments upon the fric between surfs of pine wood.† The results are given in Fig 3, merely to show how the coeff varied with vel and pres. Our table gives a coeff of .4 for pine on pine.



Line A	shows coeffs at diff vels under a pres of			1.58	lbs per sq in.		
" B	"	"	"	1.59	"	"	
" C	"	"	"	1.60	"	"	
" D	"	"	"	1.61	"	"	
" E	"	"	"	4.17	"	"	

It will be seen that at low vels the coeff decreased when the pres per sq in was almost imperceptibly increased; but this diff disappeared as the vel increased. At vels from 4 to 120 ins per sec, the coeff generally decreased as the vel increased; rapidly at first, but more slowly as the vel became greater. This agrees with other recent expts. But at very low vels (.08 to 5 ins per sec) Prof. Kimball found the coeff (line E) *increasing very rapidly with the vel.*

We have made the scale of coeffs large in order to show their variations, which are so slight that they would otherwise be scarcely perceptible. Less delicate expts would have failed to show them at all.

191. (a) In 1878 **Capt. Douglas Galton** and **Mr. George Westinghouse, Jr.,** made careful experiments in England to ascertain the effect of friction in connection **with railway brakes.**‡ The friction and pressure were

* This is not surprising in view of the extent to which the coeff is affected by the nature of the surf. If the shape of the minute projections is such that they fit into each other as perfectly under small pressures as under great ones, and if they are too strong to be broken by the pressures applied, the coeff, as stated in the 1st law, should be independent of the pres. But if high pres wedges the projections of one body more closely between those of the other, the coeff should increase under such pres. On the other hand, if the higher pres breaks down the projections while the lower ones are unable to do so, the coeff should decrease under the higher pres. The particles thus broken off may either act as a lubricant and thus still further *reduce* the fric and its coeff, or (if angular and hard) may *increase* it. Change of area of contact, under a given total pres, may, by affecting the *intensity* of the pres, make changes in the coeff similar to those just mentioned.

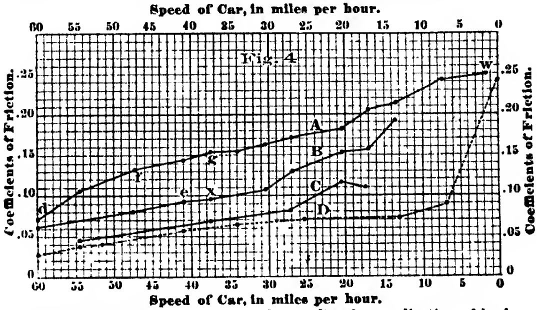
At high vels the roughnesses have not time to interlock as perfectly as at low vels. Hence we should expect a less coeff at high vels. But high vel generally increases the number of projections broken away; and these may either increase or diminish the coeff, as explained above. High vel often *indirectly* affects it by increasing the *temperature.*

† Silliman's Journal (American Journal of Science) March 1876 and May 1877.

‡ See Proc. Instn of Mechl Engrs, London, June and Oct 1878 and April 1879; and "Engineering" London, 1878; vol. 25, pp 432, 469, 490, vol. 26, pp 153, 386, 395.

automatically recorded by means of hydraulic gauges. With cast iron brake-blocks and steel-tired wooden wheels, 43⅝ inches in diameter, they found coefficients about as shown in Fig. 4.

The points in lines A, B and C show the average *brake* coeffs, or coeffs of sliding fric between the tread of a *rolling* wheel and the *brake-block*.



Line A shows brake coeffs obtained immed'y after application of brake
" B " " 5 secs " "
" C " " 15 " " "
" D shows *rail* coeffs or coeffs of sliding fric between the tread of a *sliding* or "*skidding*" wheel (held fast by the brake) and the *rail*.

(**b**) From lines A B and C it appears that the **brake coeff** obtained at a given length of time after the application of the brake was generally **greater at low than at high vels.** But where the vel was maintained uniform the **brake coeff diminished as block and wheel remained longer in contact.** Thus, lines A and B show that at 37½ miles per hour the brake coeff was .154 when the brake was first applied (point *g*), but fell to .096 in 5 secs (*x*). Line A (immed'y after application) shows a higher brake coeff (.132 at *f*) at 47½ miles than line B (5 secs after application) shows at 37½ miles (.096 at *x*).

The diminution of the *rail* coeff with length of time of application of brake was scarcely noticeable.

(**c**) When the brake fric (owing to the reduction of vel and consequent increase of coeff) becomes = the "adhesion" or static fric between the rail and the tire of the rolling wheel, the vel of rotation rapidly falls below that due to the vel of the car; *i e*, **the wheel begins to "skid"** or slide along the rail and in from .75 to 3 secs the rotation of the wheel ceases entirely.

(**d**) **The rail coeff**, line D, **is generally much less than the brake coeff**, lines A, B and C. The pres on the rail (= the wt on a wheel) was about 5000 lbs per sq in, or greatly in excess of the limit of abrasion. That at the brake was about 200 lbs per sq in. A few expts were made with brake blocks having but ⅓ of the usual area of contact, and therefore 3 times the pres per sq in under a given total pres. They failed to show conclusively that this caused any marked change in the coeff.

(**e**) **The rail coeff**, line D, like the brake coeff, **increases as the vel diminishes;** slowly at first, but much more rapidly as the speed becomes less; until, at the moment of stopping, it is generally even greater than the brake coeff just before skidding. With steel tires on *iron* rails at high vels it was somewhat greater than on steel rails, but this diff disappeared as the vel diminished.

(**f**) **Locomotives** overcome resistces = from ⅕ to ⅓ or more of the wt on all the drivers; *i e*, they have a coeff of .33 or more, although the experimental coeff for steel on steel in motion at low pres, is only about .15. But the cases are so diff that a similarity in their coeffs could hardly be expected. The great wt, say from 2 to 6 or even 7 tons, on a driver, is concentrated on a surf (where the wheel touches the rail) about 2 ins long × about ½ inch wide, or = say 1 sq in. The pres per sq in thus greatly exceeds not only that upon which the tables are based, but also the limit of abrasion. Besides, any point in the tread, during

the instant when it is acting as the fulcrum for the steam pres in the cyl, is *stationary* upon the rail. Its fric (miscalled "adhesion") is therefore *static*.

Capt. Galton found that **the coeff of "adhesion"** was independent of the vel, and depended only on the character of the surfs in contact. With a four-wheeled car having about 5000 lbs load on each wheel, it was generally over .20 on dry rails; in some cases .25 or even higher. On wet or greasy rails, without sand, it fell as low as .15 in one case, but averaged about .18. **With sand** on wet rails it was over .20. Sand applied to dry rails before starting gave .35 and even over .40 at the start, and an average of about .28 during motion; but sand applied to dry rails while the car was in motion was apt to be blown away by the movement of the car and wheels.

(g) Owing to the constancy of the coeff of "adhesion" under given conditions of tire and rail, the brake fric necessary to "skid" the wheels in any case was also practically constant for all vels. But at high vels, owing to the *lower* brake *coeff*, a *higher* brake *pres* was reqd to produce this fixed amount of brake *fric*. The skidding also reqd a longer *time* than at low speeds.

192. If the pres is sufficient to produce **abrasion** (indeed, while it is much less) the fric often varies greatly, but no precise law has yet been discovered for estimating it. Rennie gives the following **table of coeffs of fric of dry surfaces, under pressures gradually increased up to the limits of abrasion.** It will be noticed that **in this table the coeff generally increases** with the *intensity* of the pres:

Coeffs of friction of dry surfaces, under pressures gradually increased up to the limits of abrasion. (By G. Rennie, C E.)

821	......	......	......	273

193. (a) Rolling friction, or that between the circumf of a rolling body and the surf upon which it rolls, is somewhat similar to that of a pinion rolling upon a rack. In disengaging the interlocking projections, or in lifting the wheel over an obstacle *o*, Figs 5 and 6, the motive force F, instead of *dragging* one over the other, as in Fig 76, p. 407, acts at the end of a bent lever F R W Figs 5 and 6, the other end W of which acts in a direction *perp* to the contact surf; and in practical cases of rolling fric proper the leverage R W of the resisting wt of the wheel and its load is very much less, in proportion to that (F R) of the force F, than in our exaggerated figs. Hence the force F reqd to *roll* a wheel etc is usually very much less than would be necessary to *slide* it.

(b) There are usually **two ways of applying the force** in overcoming rolling fric: 1st (Fig 5) at the *axis* of the rolling body; as the force of a horse is applied at the axle of a wagon-wheel; or that of a man at the axle of a wheel-barrow: 2d (Fig 6) at the *circumf;* as when workmen push along a heavy timber laid on top of two or more rollers; or as the ends of an iron bridge-truss play backward and forward by contraction and expansion, on top of metallic rollers or balls (p725). In Fig 5 we have, in addition to the rolling fric of the circumf of the wheel on its support, the sliding fric of the axle in its bearing. In Fig 6 we have only rolling fric. but at both top and bottom of the wheel.

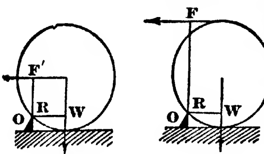

Fig. 5 Fig. 6

(c) When the obstacles *o* are very small, as in the case of cart-wheels on smooth hard roads, or of car-wheels on iron or steel rails, the leverage

(F R) of F becomes, practically, in Fig 5 the *radius*, and in Fig 6 the *diam*, of the wheel; while that (R W) of the resistce is very small. Hence, neglecting axle fric in Fig 5, the force F reqd to overcome rolling fric in such cases is directly as the wt W of and on the wheel, and inversely as the diam of the wheel.

The few expts that have been made upon the coeffs of rolling fric, apart from axle fric, are too incomplete to serve as a basis for practical rules.

(d) The fric (or "**adhesion**") between wheel and rail, which enables a locomotive to move itself and train, or which tends to make a car-wheel revolve notwithstanding the pres of the brake, is a resistce to the *sliding* of the wheel on the rail; and is therefore not rolling but *sliding* fric; *static* when the wheels either stand still or roll perfectly on the rails; and *kinetic* when they slip or "skid".

194. The friction of liquids moving in contact with solid bodies is independent of the pressure, because the "lifting" of the particles of the fluid over the projections on the surf of the solid body, is aided by the pres of the surrounding particles of the liquid, which tend to occupy the places of those lifted. Hence we have, for liquids, no coeff of fric corresponding with that (= resistce ÷ pres) of solids. The resistce is believed to be directly as the area of surf of contact. Recent researches indicate that Resistce = a coeff × area of surf × vel^n, in which both n and the coeff depend upon the vel and upon the character of the surf; and that at low vels $n = 1$, but that at a certain "critical" vel (which varies with the circumstances) n suddenly becomes = 2, owing to the breaking up of the stream into marked counter currents or eddies. The resistance of fluid fric arises principally from the counter currents thus set in motion, and which must be brought into compliance with the direction of the force which is urging the stream forward.

195. Table of coefficients of moving friction of smooth plane surfaces, when kept perfectly lubricated. (Morin.)

The launching friction of the wooden frigate Princeton was found by a committee of the Franklin Institute in 1844, to average about .067 or one-fifteenth of the pressure during the first .75 of a second and .022 or one forty-fifth for the next 4 seconds of her motion. The slope of the ways was 1 in 13, or 4 degrees 24 minutes. They were heavily coated with tallow. Pressure on them = 15.84 lbs. per square inch, or 2280 lbs. per square foot. In the first .75 of a second the vessel slid 2.5 inches; in the next 4 seconds 15 feet 6.5 inches; total for 4.75 seconds 15.75 feet.

196. The friction of lubricated surfaces varies greatly with the character of the surfs and with that of the lubricant and the manner of its application. If the lubricant is of poor quality, and scantily and unevenly applied under great pres, it may wear away in places and leave portions of the dry surfs in contact. The conditions then approximate to those of unlubricated surfaces. But if the best lubricants for the purpose are used, and supplied regularly and in proper quantity, so as to keep the surfs always perfectly separated, the case becomes practically one of liquid friction, and the resistce is very small. Between these two extremes there is a wide range of variations (see table, ¶ 197 (*d*)), the coeff being affected by the smallest change in the conditions. Where any degree of accuracy is reqd, we would refer the reader to the experimental results given in Prof. Thurston's very exhaustive work,* devoted exclusively to this intricate subject.

197. (a) Expts by Mr. Arthur M. Wellington upon the **fric of lubricated journals** † gave a gradual and continuous increase of coeff as the vel of revolution diminished from 18 ft per sec (= a car speed of 12 miles per hour) to a stop. This increase was very slight at high vels, but much more rapid at low ones; as in Figs 3 and 4. At vels from 2 to 18 ft per sec the coeff was much less under high pressures than under low ones; but at starting there was little diff in this respect. The coeff increased rapidly as the **temperature** rose from 100° to 120° and 150° Fahr.

(b) Prof. Thurston, also experimenting with **lubricated journals**, ‡ found that at starting, the coeff increased with increase of pres, as it did also when in motion, if the pres greatly exceeded the max (say 500 to 600 lbs per sq in) allowable in machinery. He also found that at high vels the coeff *increased* very slowly (instead of continuing to decrease) as the vel increased.

(c) Prof. Thurston gives the following **approx formulæ for journal friction** at ordinary temperatures, pressures and speeds, with journal and bearing in good condition and well lubricated:

$$\textbf{Coeff for starting} = (.015 \text{ to } .02) \times \sqrt[3]{\text{pres in lbs per sq in.}}$$

$$\textbf{Coeff} \text{ when the shaft is } \textbf{revolving} = (.02 \text{ to } .03) \times \frac{\sqrt[5]{\text{vel in ft per } min}}{\sqrt[2]{\text{pres in lbs per sq in.}}}$$

At pressures of about 200 lbs per sq in:

$$\textbf{Temperature of minimum fric}\text{; in Fahr degs} = 15 \times \sqrt[3]{\text{vel in ft per min}}$$

Caution. The leverage, with which journal fric resists motion, **increases with the diam** of the journal.

(d) The following figures, selected from a table of experimental results given by Prof. Thurston, merely show **the extent to which the coeff of journal fric is affected by pres, vel and temperature:** and hence the risk incurred in rigidly applying general rules to such cases. In these expts the character of journal and bearing, the lubricant and its method of application, remained the same throughout. Where these vary, still further, and much greater, variations in the coeff may occur.

Steel journal in bronze bearing, lubricated with standard sperm oil.

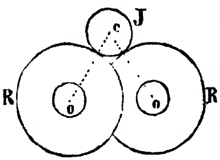
* Friction and Lost Work in Machinery and Mill Work. John Wiley & Sons, New York.
† Trans Amer Soc of Civil Engrs New York Dec. 1884.
‡ [illegible]

(e) **Where the force is applied first on one side of the journal and then on the opposite side,** as in crank pins, the fric is less than where the resultant pres is always upon one side, as in fly-wheel shafts because in the former case the oil has time to spread itself alternately upon both sides of the journal.



(f) **Friction rollers.** If a journal J, instead of revolving on ordinary bearings, be supported on friction rollers R, R, the force required to make J revolve will be reduced in nearly the same proportion that the diam of the axle *o* or *o* of the rollers, is less than the diam of the rollers themselves.

Mr. Wellington experimented with a patent bearing on this principle, invented by Mr. A. Higley. Diam of rollers R R, 8 ins; of their axles *o o* 1¾ ins; of the journal *c*, 3½ ins. Here. theoretically,

$$\text{fric of patent journal} = \text{fric of } 3\tfrac{1}{2} \text{ in journal} \times \frac{\text{diam of axles } oo}{\text{diam of rollers RR}} = \frac{1\tfrac{3}{4} \text{ ins}}{8 \text{ ins}}$$

or as 1 to 4.6. Under a load of 279 lbs per sq in, Mr. Wellington found it about as 1 to 4 when starting from rest; and about as 1 to 2 at a car speed of 10 miles per hour.

198. (a) **Resistance of railroad rolling stock.** This consists of rolling fric between the treads of the wheels and the rails (the treads also sometimes *slide* on the rails, as in going around curves); of sliding fric between the journals and their bearings, and between the wheel flanges and the rail heads; of the resistce of the air; and of oscillations and concussions, which consume motive power by their lateral and vert motions, and also increase the wheel and journal frics.

Its amount depends greatly upon the condition of the road-bed and rails (as to ballast, alignment, surf, spaces at the joints, dryness etc); upon that of the rolling stock (as to wt carried, kind of springs used, kind and quantity of lubricant, condition and dimensions of wheels and axles etc); upon grades and curvature; upon the direction and force of the wind; and upon many minor considerations. Experiments give very conflicting results.

(b) During the summer of 1878, **Mr. Wellington** experimented with loaded and empty box and flat freight cars, passenger and sleeping cars, and at speeds varying from 0 to 35 miles per hour. The cars were started rolling (by grav) down a nearly uniform grade of .7 foot per 100 feet, or 36.5 feet per mile, and 6400 ft long. Their resistces were calculated as in ¶ 185. "The rails were of iron, 60 lbs per yd, and the track was well ballasted and in good line and surf, but not strictly first class." The following approx figures are deduced from Mr. Wellington's expts upon cars fitted with ordinary journals:*

Car Resistance in pounds per ton (2240 lbs) of weight of train, on straight and level track in good condition.

Speed of train in miles per hour	Empty cars				Loaded cars			
	Axle, tire and flange	Oscillation and concuss'n	Air	Total	Axle, tire and flange	Oscillation and concuss'n	Air	Total
0	14	0	0	14	18	0	0	18
10	6	.6	.4	7	4	.6	.4	5
20	6	2.7	1.3	10	4	2.	1.	7
30	6	5.3	2.7	14	4	4.7	2.2	11

(c) With the Higley patent anti-fric roller journal, the resistce to *starting* was but about 4 lbs per ton.

(d) About midway in the track experimented upon, was a **curve of 1° deflection angle** (5730 ft rad) 8000 ft long, with its outer rail elevated 3 to 4 ins

* Transactions, American Society of Civil Engineers, Feb 1879.

above the inner one. The rise of the outer rail was begun on the tangent, about 500 ft before reaching the curve. In the first 500 ft of the curve the resistce was greater than that encountered just before reaching the curve, by from .6 to 2.1 (average 1.1) lbs per ton. In the last 500 ft of the curve this excess had diminished to from .2 to .9 (average .6) lbs per ton. Owing to the continuance of the down grade on the curve, the vel increased as the train traversed the curve; but it does not clearly appear whether the decrease in curve resistce was due to the increase in vel, or to the fact that the oscillations caused by entering the curve gradually ceased as the train went on.

(e) **Mr. P. H. Dudley,** experimenting with his **"dynagraph"*** obtained results from which the following are deduced:

Train Resistance in pounds per ton (2240 lbs) of weight of train, including grades.

Description of train			Trip	Average speed. Miles per hour	Average resistance.
Loaded cars	Empty cars	Weight tons (2240 lbs)			
29	2	526	Toledo to Cleveland. 95 miles	20	8.34
37	0	633	Cleveland to Erie 95.5 miles	20	7.67
25	2	458	Erie to Buffalo. 88 miles	20	8.89

"With the long and heavy trains of the L. S. & M. S. Ry, of 600 to 650 tons, it reqd less fuel with the same engine to run trains at 18 to 20 miles per hour than it did at 10 to 12 miles per hour", owing to the fact that at the higher speeds steam was used expansively to a greater extent, and hence more economically.

199. The work, in ft-lbs, reqd to overcome fric through any dist, is = the fric in lbs × the dist in ft. In order that a body, started sliding or rolling freely on a hor plane and then left to itself, may do this work; i e, may slide or roll through the given dist, its kinetic energy (= its wt in lbs × its vel² in ft per sec ÷ 2*g*†) must = the first-named prod. Conversely, **the dist in ft** through which such a body will slide or roll on a hor plane, is

$$= \frac{\text{its kinetic energy in ft-lbs, at start}}{\text{fric in lbs}}$$

$$= \frac{\text{wt of body in lbs} \times \text{initial vel}^2 \text{ in ft per sec}}{\text{wt of body in lbs} \times \text{coeff of fric} \times 2g\dagger} = \frac{\text{initial vel}^2 \text{ in ft per sec}}{\text{coeff of fric} \times 2g}$$

The time reqd, in secs, is $= \frac{\text{dist in ft, so found}}{\text{mean vel, in ft per sec}} = \frac{\text{dist in ft}}{\frac{1}{2}\text{ initial vel in ft per sec}}$

Suppose two similar locomotives, A and B, each drawing a train on a level straight track; A at 10 miles, and B at 20 miles, per hour. The total resistce of each eng and train (which, for convenience, we suppose to be independent of vel) is 1000 lbs. Hence the force, or total steam pres in the two cyls reqd to balance the fric and thus maintain the vel, is the same in each eng. In traveling *ten miles* this force does the same amount of work (1000 lbs × 10 miles = 10000 pound-miles) in each eng, and with the same expenditure of steam in each; although B must supply steam to its cyls *twice as fast* as A, in order to *maintain* in them the same pres. In *one hour* the force in A does 10000 lb-miles as before, but that in B does (1000 lbs × 20 miles =) 20000 lb-miles, and with twice A's expenditure of steam.

But in fact the resistce of a given train is much greater at higher vels. See table, ¶ 198 (*b*) And even if we still assumed the resistce to be the same at both vels, B must exert more force than A in order to *acquire* a vel of 20 miles per hour while A is acquiring 10 miles per hour.

* An inst for measuring the strain on the draw-bar of a locomotive, or the force which the latter exerts upon the train.
† g = acceleration of gravity = say 32.2 : $2g$ = say 64.4.

200. Natural Slope. When granular materials, as sand, earth, grain, etc., are deposited loosely, as when they are shoveled from a cutting or dumped from a cart, the angle, formed between a level plane and the sloping surface of the pile of material, is called the natural slope. This angle depends upon the friction and adhesion between the separate particles of the material, and often varies, in one and the same material, from time to time, with changes in weather conditions, etc., especially with dampness.

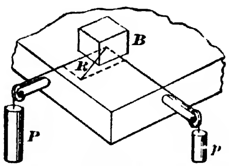


Fig. 85.

201. Any force, p, Fig. 85, acting upon a body, B, will suffice to move the body (see foot-note (*), ¶ 1), provided it exceeds the sum, S, of all resistances, including friction between B and the surface upon which B rests, or if it forms, with any other force or forces, P, a resultant, R, greater than S.

If, before the application of p, the body is already in uniform motion, P is = S; and any force, p, however small, will suffice to change the direction of motion. This accounts for the ease with which a *revolving* shaft may be slid longitudinally in its bearings, and for the fact that a cork may be more easily drawn if we first give it a twisting motion in the neck of the bottle.

LEVERS.

202. Classes of Levers. Figs 86. Levers are classed according to the relative positions of "power," * "weight" * and fulcrum, as follows:

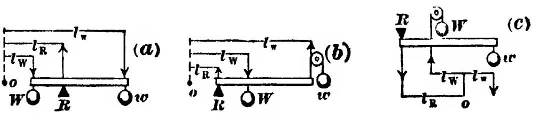

Fig. 86.

Fig. (*a*), Class 1. Fulcrum R between power w and weight W;
" (*b*), " 2. Weight W between power w and fulcrum R;
" (*c*), " 3. Power W between weight w and fulcrum R.

In class 2, the leverage of the power is necessarily greater than that of the weight. In class 3, vice versa.

203. In Fig. 86, taking the moments of the forces about any point at pleasure, as o, we have, for equilibrium:

$$\text{Fig. } (a),\ W \cdot l_W - R\, l_R + w \cdot l_w = 0;$$
$$\text{Fig. } (b),\ W \cdot l_W - R\, l_R - w \cdot l_w = 0;$$
$$\text{Fig. } (c),\ W \cdot l_W - R\, l_R + w \cdot l_w = 0.$$

---

* When levers are used for lifting weights or for overcoming other resistances, the force applied is called the "power," and the resistance to be overcome is called the "weight."

204. Compound levers, Fig. 87, may be used where there is not room for the arms of a single lever of sufficient length. In a compound lever, neglecting friction,

$$\frac{\text{weight}}{\text{power}} = \frac{\text{product of lengths of power arms}}{\text{product of lengths of weight arms}} = \frac{8 \times 10 \times 2}{2 \times 1 \times 4} = \frac{160}{8} = 20$$

The three levers of Fig. 87, taken separately and beginning at the power end, give:

$$\frac{\text{weight}}{\text{power}} = \frac{8}{2} = 4, \quad \frac{10}{1} = 10, \quad \frac{2}{4} = \frac{1}{2},$$

and $4 \times 10 \times \frac{1}{2} = 20$, as before.

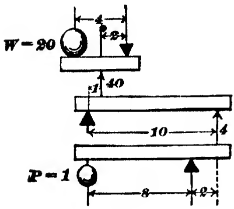

Fig. 87.

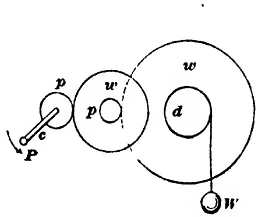

Fig. 88.

205. Toothed or Cog Gearing. Wheels and Pinions. Fig. 88. These are a series of continuous compound levers. The power is usually applied to a crank, *c*, and the weight is attached to a drum, *d*. The larger wheel, *w*, on a given shaft, is called the wheel; the smaller one, *p*, the pinion.

Let c = the radius of the crank, d = that of the drum, m = the product of the radii of the pinions, and n = the product of the radii of the wheels. Then, neglecting friction,

$$\frac{\text{weight}}{\text{power}} = \frac{c \, . \, n}{m \, . \, d}.$$

Instead of the several radii, we may of course use the corresponding diameters or circumferences; and, as the teeth are necessarily of equal "pitch" (length, measured along the circumference), the number of teeth on a wheel or pinion is usually taken instead of the radius.

When the ratio, $\frac{\text{weight}}{\text{power}}$, is great, the system is said to be of **high gear.** When that ratio is small, we have **low gear.**

Compound levers and gearing are used for converting low into high velocity, as well as for lifting great weights by means of small powers. When used for increasing the velocity, the positions of power and of weight are the reverse of those shown in Figs. 87 and 88.

206. Whenever the power and the weight balance each other, either in a single lever, or in a connected system of levers or leverages, of any kind whatever, then if we suppose them to be put into motion about the fulcrum, their respective velocities will be in the same proportion or ratio as their leverages; that is, if the leverage of the power is 2, 5, or 50 times as great as that of the weight, the power will move 2, 5, or 50 times as fast as the weight. Therefore, by observing these velocities, we may determine the ratio of the leverages. The weight and the power are to each other, therefore, *inversely* as their velocities, as well as inversely as their leverages.

207. No mechanical advantage is gained by merely increasing the *length* of a lever, as by curving it, as at *abo*, Fig. 4, ¶ 13, or by giving it an inclination to the line of action of the power, P, as at *o m*, *o u* or *o n*.

208. Thus, in Fig. 89, representing a bent lever, $a\,f\,b$, the *length* of the *lever*, or of any of its members, as $f\,b$, must not be confounded with the *arm* or *leverage* of the *force* acting upon the lever. These may or may not be equal. Thus, the member $f\,b$ is much longer than the member $f\,a$; yet, if the arms, $f\,a$ and $f\,c$, of the forces or weights are equal, the weights n and m must also be equal in order to insure equilibrium

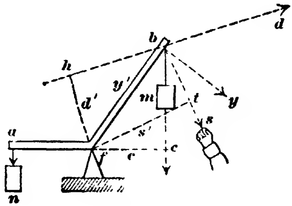

Fig. 89.

209. If the weight m be removed, a force c, or s, or y, or d, with leverage $= c', s', y', d'$, respectively, may be applied at any point, as b, to balance the moment of n. In any case this force must be such that

$$\text{force} \times \text{its leverage} = n\ a\ f.$$

Hence,

$$\text{force} = \frac{n\ a\ f}{\text{leverage of force}}.$$

210. Hence also the force required is *least* when, as at y, it is *perpendicular* to the length of the member $f\,b$; for the leverage (which evidently *cannot exceed* $f\,b$) is then greatest. The force required increases as it deviates in either direction from the line $b\,y$ (perpendicular to $f\,b$) and approaches more nearly to the direction of $f\,b$ itself; for its leverage then constantly decreases. No force, however great, could balance the moment of n about f, if applied in the direction $f\,b$, or $b\,f$; for such a force would have no moment about f.

211. Similarly, in Fig. 90, the moment, about a, of a load W, placed at b is $=$ W . $a\,c$, or the same as if it were placed at c, and not $=$ W . $a\,b$.

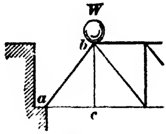

Fig. 90.

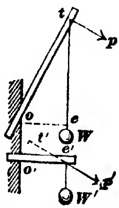

Fig. 91.

212. In Figs. 91, also, the moments W. $o\,e$ and W'. $o'\,e'$, of the equal weights, W and W', are equal. But if forces, p and p', be applied in directions perpendicular to the longer beam, $o\,t$, the leverage $o\,t$ of p becomes about 6 times that ($o'\,t'$) of p'. Hence a force, p, applied at t, has about the same bending moment as a parallel force $= 6\,p$, applied at e'.

STABILITY.

213. Stability. Figs. 92. If the resultant, R, Fig. (*a*), of the force P and weight W, falls beyond the base, as shown, then the overturning moment of P, Fig. 92 (*b*), about the toe *n*, will exceed the moment of stability of the weight W about the same point, and the body will overturn about *n*. If not, it will stand.

214. Assuming stability against overturning, the body will slide if the horizontal component, *h*, of R, Fig. 92 (*a*), exceeds the frictional and other resistances.

215. In practice, the toe, *n*, or the ground beneath it, might yield if the stone revolved upon it, or if R fell near *n* (see ¶¶ 145, etc.); but this is a question of strength of materials. Cement, clamps, etc., between the base and the ground, would add a third force, and thus change the problem.

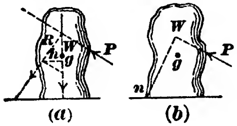

Fig. 92.

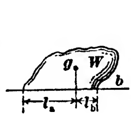

Fig. 93.

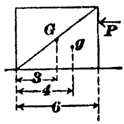

Fig. 94.

216. Owing to the greater leverage, l_a, Fig. 93, of W about *a*, the moment of stability is much greater about *a* than about *b*.

217. In Fig. 94, let G = 2 lbs.; *g* = 1 lb.; leverages = 3, 4 and 6 ft., as shown. Then the moment of stability of the rectangular body, G, against a horizontal force, P, is = 3 G = 3 × 2 = 6 ft.-lbs.; and the moment of the lower triangular body, *g*, is = 4 *g* = 4 × 1 = 4 ft.-lbs.; so that, although the larger body weighs twice as much as the smaller one, yet its moment of stability is only 1.5 times as great.

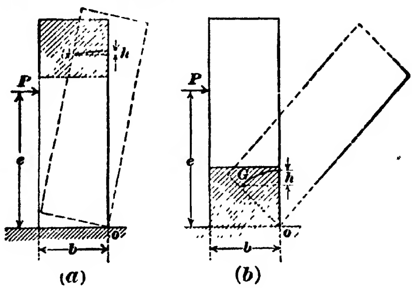

Fig. 95.

218. Work of Overturning. In Figs. 95 (*a*) and (*b*), let the shaded portion of each figure be of lead, and the remainder of wood, and let the center of gravity of the entire body, in each case, be at G. Then, since the weight, W, is the same in both cases, as is also its leverage of stability, about o, $= \frac{b}{2}$, the moment of stability, $= \frac{1}{2} b.W$, is the same in both cases, as is also the force, P, required to balance that moment when applied at a given elevation, *e*. As overturning proceeds, the weight, W, remaining unchanged, the leverage and moment of stability, and the overturning moment required, decrease, becoming = 0 when the bodies reach the positions

shown by the dotted lines. If the elevation, e, remains constant, the force, P, required for overturning, decreases in the same proportion as the leverage, etc.

219. But in order that the bodies may be overturned by the force of gravity alone, they must be brought into the positions shown by the dotted lines. This requires that the weights of the bodies be lifted through a height = the distance, h, through which their centers of gravity, G, are raised. Hence

$$\text{work of overturning} = W . h.$$

Since h is greater in Fig (*b*), the work of overturning is greater in that case.

In civil engineering we are generally concerned with the amount of the *force* which will *begin* overturning, rather than with the amount of *work* required to *complete* the overthrow

220. Stability against overturning is of course affected, and may be increased, by forces other than the weight of the body itself. Thus, the stability of a bridge pier is ordinarily increased by the weight of the bridge itself if this be brought upon the pier symmetrically. Otherwise the weight of the bridge may either increase or diminish the stability of the pier, according to circumstances.

221. The coefficient of stability, in any given case, is the ratio of the moment of stability to the overturning moment. Or,

$$\text{Coefficient of stability} = \frac{\text{moment of stability}}{\text{overturning moment}}.$$

222. Let the weight, W, of the stone in Fig 96 be 10 lbs., G its center of gravity, and $o\,g$ = 2 feet. Then the moment of the weight about o, or the moment of stability about o, is 10 × 2 = 20 ft.-lbs.; and, if $o\,n$ = 5 feet, a force $P = \frac{20}{5} = 4$ lbs., will just hold in equilibrium the moment of the weight, so that, except at the corner, o, no pressure will be exerted upon the base $o\,m$, although the stone remains in contact with the base. If the force P exceeds 4 lbs, the stone will begin to turn about o. If P is less than 4 lbs., the stone will exert a pressure upon the base $o\,m$.

Let the stone be supported at o and at m only. The leverage of the supporting force R, at m, is = the length $o\,m$ of the base, = l. Let P = 1 and base $o\,m$ = 4.5 ft. Then, for equilibrium,

$$W . o\,g - P . o\,n - R . o\,m = 0;$$

or,

$$20 \text{ ft.-lbs} - 1 \times 5 = 1.5 \times R;$$

or,

$$R = \frac{20 - 5}{4.5} = 3.33 \ldots \text{ lbs.}$$

In other words, a vertical upward force, R, of 3.33 . . . lbs., at m, will maintain equilibrium.

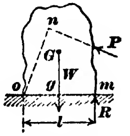

Fig. 96.

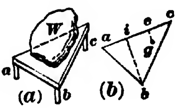

Fig. 97.

223. In Fig. 97 (*b*), let g be the center of gravity of the load W and the table, combined, Fig 97 (*a*). Then, upward reaction of $b = \frac{W . e\,g}{i\,b}$. Those of a and c may be similarly found.

224. In Fig. 98, let h be the horizontal force exerted at the crown by the left-hand half of the arch, against the half-arch shown, and e its leverage about o. Let W be the weight of the half-arch with its spandrel, acting as a single rigid body, and l its leverage about o. Then, for equilibrium, we have

$$h \cdot e = W \cdot l; \text{ or } h = \frac{W \cdot l}{e}.$$

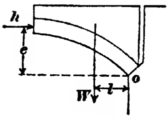

Fig. 98.

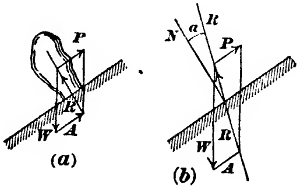

Fig. 99.

Stability on Inclined Planes.

225. Stability on Inclined Planes. Fig. 99. Here, as in ¶ 213, if the resultant, R, of the force P and weight W, falls beyond the base,—*i. e.*, if the overturning moment exceeds the moment of stability,—the body will overturn. If not, it will stand.

The force, P, in any given direction, required to prevent overturning, is = the anti-resultant, A, of weight W and reaction R; and reaction R = anti-resultant of force P and weight W.

226. Neglecting friction, as in Fig. 99 (a), R will be normal to the plane. Taking friction into account, Fig. 99 (b), R may form, with a normal, N, to the plane, an angle, a, not exceeding the angle of friction between the body and the plane. R may be either uphill or downhill from N.

227. In Fig. 100, the body B has less stability against overturning about its toe, a, than has the similar body, A, when the force, n, tends to upset it downhill; but a greater stability than A against overturning about c under the action of a force tending to upset it uphill.

228. The body C, which would upset if upon a horizontal base, would be stable against overturning if placed upon an inclined plane, as at D. Assuming $a\,o = t\,c$, a given upward vertical force would have the same overturning

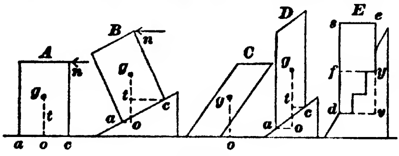

Fig. 100.

moment, whether applied at a or at c. But a given horizontal force, applied at any given height, as at g, has a greater leverage, $g\,o$, when pushing downhill than when pushing uphill. In the latter case its leverage is only $g\,t$.

229. Structures built upon slopes are liable to slide. This may be obviated by cutting the slope into horizontal steps, as at $d\,y$, Fig. E; but the vertical faces of such steps break the bond of the masonry; and, moreover, the joints being more numerous, and the mortar therefore in greater quantity, on the deeper side, $s\,d$, than on the shallower uphill side, $e\,y$, the structure is liable to unequal settlement, the downhill side settling most and tending to split away from the uphill portion, as might be the case with a founda-

tion firm in some parts and compressible in others. Hence, when circumstances permit, it is preferable to level off the foundation, as at $d\,v$; or, if the structure has to withstand downhillward pressures, v should be lower than d, and the courses of masonry laid with a corresponding inclination.

THE CORD.

230. The Cord. Figs 101 (*a*) and (*b*) and 102 (*a*) and (*b*). In ¶¶ 230 to 239 we deal with cords supposed to be perfectly flexible, inextensible, frictionless, weightless and infinitely thin.

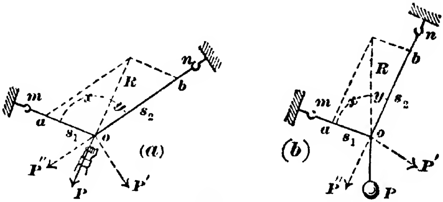

Fig. 101.

231. Let P be the external force applied to the cord at the knot or pin, o, and let R be the resultant of the stresses, s_1 and s_2, or $o\,a$ and $o\,b$, in the two segments, $o\,m$ and $o\,n$, of the cord. Then, for equilibrium, R must be equal to and colinear with P.

232. Knowing the amount of P (= R), the tensions s_1 and s_2 may be found by means of ¶ 36; and, vice versa, given s_1 and s_2, we may find R (= P) by ¶ 35. Or see ¶ 40.

233. If, as in Figs. 101 (*a*) and (*b*), the force P be applied to the cord, at o, by means of a fixed knot, incapable of sliding along the cord, so that the segments, $o\,m$ and $o\,n$, of the cord, are of fixed lengths, and the angle, $x + y$, between them, of fixed magnitude, then the force may be applied in any direction, as P or P′, passing between the two segments of the cord; and the components, s_1 and s_2, will be equal only when R (P produced) forms equal angles, x and y, with the two segments of the cord. If the direction of the force, as P″, coincides with either segment, as $o\,n$, of the cord, that segment transmits the entire force, P″, and the other segment none.

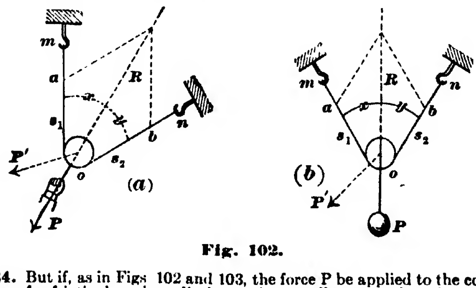

Fig. 102.

234. But if, as in Figs 102 and 103, the force P be applied to the cord by means of a frictionless ring, slip-knot, pin or pulley, etc., then, for equilibrium, the two stresses, s_1 and s_2, must be equal, as must also the two angles, x and y; and, if we suppose the direction of the force P to be changed, as to P′, the pin and the cord will readjust themselves, as indicated by the dotted lines in Fig. 103, until the pin finally comes to rest at that point, o', where the angles, x' and y', are equal, and also the stresses, s_1' and s_2'.

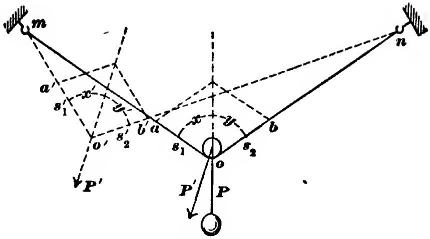

Fig. 103.

235. Even though the pin or pulley be rigidly fixed to some external object, as at o, Fig. 104, yet, if there is no friction at its axle, or between it and the cord, the components, s_1 and s_2, will still be equal, and their resultant, R, will bisect the angle, $x + y$, between them. In other words, the angles, x and y, will be equal.

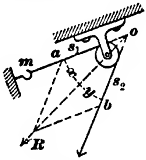

Fig. 104.

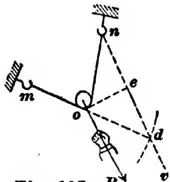

Fig. 105. P

236. When the pin is movable, Figs. 102 and 103, to find the position, o, Fig. 105, which it will assume. From the end, n, of one of the segments, $o\ n$, of the cord, draw $n\ v$ parallel to P. From the end, m, of the other segment, with radius $= m\ o + o\ n$, $=$ length of cord, describe an arc, cutting $n\ v$ in d. Bisect $n\ d$ in e. Draw $e\ o$ normal to $n\ v$, intersecting $m\ d$ in o. Then o is the required point.

237. Whether o be a fixed knot or a movable pin or pulley, it is always in the circumference of an ellipse whose foci are at the ends, m and n, of the cord.

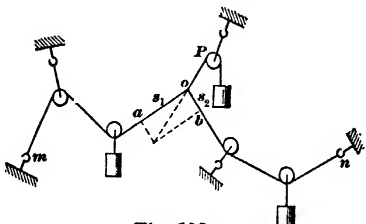

Fig. 106.

238. From the foregoing it follows that, if o, Fig. 106, be a fixed knot, and if the other pins or pulleys, etc., are frictionless, the stress $a\ o$, or s_1, will be transmitted uniformly throughout the left segment of the cord, from o to its end at m; and $b\ o$, or s_2, throughout the right segment, from o to n.

239. Caution. Note that, in Fig. 107 (*b*), the stresses in all the cords are twice as great as the stresses in the corresponding cords in Fig. 107 (*a*), although each Fig. shows a load = 4 suspended from the pulley. Thus, if the weight be that of a man, hanging by the rope, and if the rope, in Fig. (*a*), be just sufficiently strong to hold, it will break if he gives one end of the rope to another man to hold, or makes it fast, as in Fig (*b*).

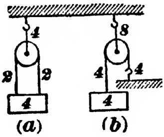

Fig. 107.

The Funicular Machine.

240. When the angles, x and y, Figs. 101, etc., are very great, a very small force, P, will balance a very great stress, s_1 or s_2, in the cord. When $x = y = 90°$, we have $\cos x = \cos y = 0$, and $s_1 = s_2$ = infinity, however small P may be If a line, $m\ n$, joining the ends of the cord, is horizontal or inclined, the weight of the cord itself acts as a force P. Hence

"There is no force, however great, can stretch a cord, however fine, into a horizontal line that shall be absolutely straight."

241. The funicular machine takes advantage of the fact that, when the total angle, $x + y$, between the two segments of the cord, approaches 180°, a small force, P, may balance great stresses, s_1 and s_2 Thus, in Fig 108, let W represent a heavy boat (seen in plan) which is to be hauled ashore. One end of a rope being made fast to the bow of the boat, the rope is passed around one smooth post, n, to another, m, around which it is given one or more whole turns; and a man stands at the end, e, to take in the slack; while others, taking hold of the rope between m and n, pull it, in the direction of P, into a position $m\ o\ n$. If the two angles, x and y, are equal, the component in the segment $o\ n$ exceeds P, so long as the angle x exceeds 60°, and a pull, equal to this component (except in so far as it is reduced by the rigidity of the rope and by its friction against the post n), is exerted upon the boat at W, drawing it a short distance up the beach. The rope is then straightened again, from m to n, by taking in the slack at e, and the operation is repeated as often as may be necessary.

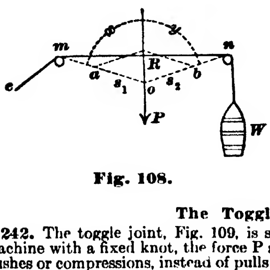

Fig. 108.

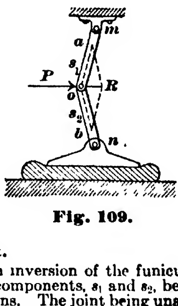

Fig. 109.

The Toggle Joint.

242. The toggle joint, Fig. 109, is simply an inversion of the funicular machine with a fixed knot, the force P and the components, s_1 and s_2, being pushes or compressions, instead of pulls or tensions. The joint being unable to move along the arms, the force P may be applied in any direction at pleasure, but it is usually exerted in a directio' forming approximately equal angles with the two arms.

The Pulley.

243. Figs. 110 show the relations of stresses and weights in several arrangements of fixed and movable pulleys. Thus, in (*a*), 1 lb. balances 1 lb., in (*b*) 2 lbs., in (*c*) and in (*d*) 4 lbs. In each case, if the bodies or weights be set in motion, their velocities are inversely as their masses. See ¶ 206.

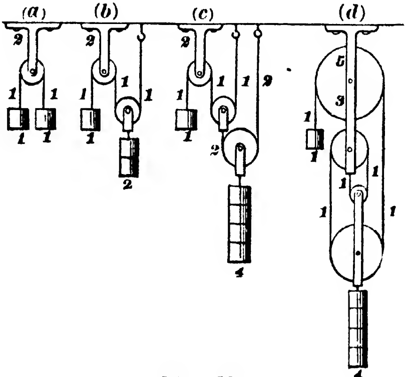

Fig. 110.

244. The simple pulley, Fig. 110 (*a*), is used simply for convenience of changing direction of stress, for the forces at the two ends of the cord are equal; but in the compound pulley, Figs 110 (*b*), (*c*), (*d*), a small force (the "power"), moving rapidly, at one part of the rope, balances a greater force (the "weight"), moving slowly, at another part Hence, the compound pulley is used for the purpose of overcoming great resistances slowly, by means of small forces, moving rapidly.

245. To set such a system in motion * (*i e*. to raise the "weight") requires that the equilibrium be disturbed by making the "power" exceed the stress in the cord due to the "weight" But the motion, once generated, will continue indefinitely if the "power" is made sufficiently greater than the "weight" to balance the resistances of friction, etc.

The Loaded Cord or Chain.

246. In Figs. 111 the principle of the cord polygon, ¶¶ 86, etc., is applied to the case of a flexible cord or chain, sustaining four loads, $p_1 \ldots p_4$, at fixed points, and exerting a horizontal † pull, H, at its lower end, and an inclined pull, R, at its upper end. The loads, $p_1 \ldots p_4$, are represented by the vertical line, 0–4, Fig. 111 (*a*); the horizontal pull, H, by 0–*c*; the amount and direction of the inclined pull, R, at the upper end of the cord, by 4–*c*, and the tensions in the segments, 1–2, 2–3 and 3–4, by the rays, 1–*c*, 2–*c* and 3–*c*, respectively.

247. The horizontal tension, H (= the horizontal component of the tension in each segment), is uniform throughout the cord; but the vertical component of the tension in any segment is equal to the sum of the loads between that segment and the pulley, *m*. Thus, the vertical component

---

* See foot-note (*), ¶ 1.

† See foot-note (*), ¶ 249.

(0–2, Fig. a) of the tension, c–2, in segment 2–3, is $= p_1 + p_2$; that in segment 3–4 is $0–3 = p_1 + p_2 + p_3$, etc.

248. If all the loads (including W) be increased in the same proportion, as indicated by the dotted lines in Fig. 111 (a), or diminished in the same proportion, the new triangles, c' 4′ 0, etc., Fig (a), will be similar to the old, and the profile of the cord, Fig. (b), will remain unchanged, although the stresses in its segments will of course be increased or diminished in the same proportion.

249. In Fig. 111 we make the weight, W, which is necessarily equal to the horizontal* pull, H (see The Cord, ¶¶ 230, etc.), equal also to the

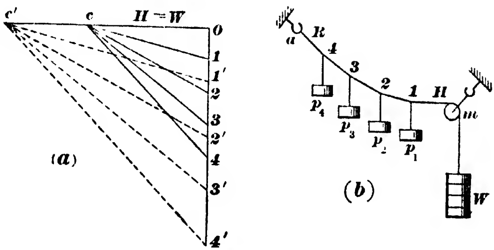

Fig. 111.

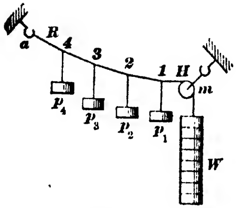

Fig. 112.

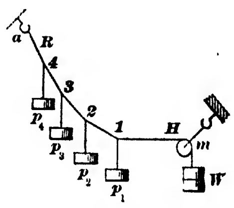

Fig. 113.

sum of the loads, $p_1 \ldots p_4$. When this is the case, the cord segment, a–4, next to the support, a, and the corresponding line, c–4, Fig. (a), will be inclined 45° to the vertical.

250. But if, while the loads, $p_1 \ldots p_4$, remain unchanged, we raise the pulley m, so as to keep H horizontal,* we shall obtain a flatter curve, as in Fig 112; and, for equilibrium, H (= W) must be made *greater* than the sum of $p_1 \ldots p_4$. On the other hand, if we place the pulley, m, lower than in Fig. 111 (still keeping H horizontal), we obtain a deeper curve, as in Fig 113; and H (= W) must be made *less* than the sum of $p_1 \ldots p_4$.

---

* In Figs. 111, 112 and 113 we suppose the weight, W, and the position of the pulley, m, to be so adjusted, relatively to the support, a, that the pull, H, shall remain horizontal.

ARCHES, DAMS, ETC. THRUST AND RESISTANCE LINES.

The Arch.

In ¶¶ 251 to 257 are given the elements of the commonly accepted theory of the arch. For practical considerations, see ¶¶ 258 to 266, and Stone Bridges.

251. If Figs. 111, 112 and 113 be inverted, the cord segments will represent struts, sustaining compression, as do the stones of a masonry arch, Fig. 114.

Thrust Line. Resistance Line.

252. In the case of an arch, Fig 114, assuming * that the horizontal thrust H, at the crown, *m*, and the reaction, R, of the skewback, *a*, act at the center (or at some other definite point) of crown and of skewback, respectively, their amounts, and the direction of the reaction, R, may be found by means of the Force Triangle, ¶ 51, or by Moments, ¶ 224. (See ¶ 257.) We then suppose the half-arch and its spandrel to be divided, by vertical planes,* Fig.

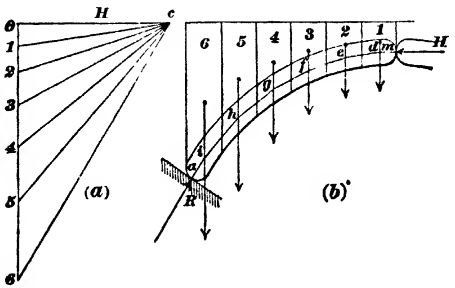

Fig. 114.

114 (*b*), into a number of segments, as shown; and, finding the weight and the center of gravity of each such segment (see ¶¶ 257 and 266), we treat these segments as we treated the loads, $p_1 \ldots p_4$, of Figs. 111 to 113, laying them off from 0 to 6, Fig. 114 (*a*), and laying off 0–*c* horizontal and = H. The rays, *c*–1, *c*–2, etc., then give, theoretically,* the directions and amounts of the pressures exerted by the segments, 1, 2, etc., respectively.

The broken line, *m d e f . . . . a*, Fig. 114 (*b*), thus formed, is called the **thrust line,** or line of resultants. It corresponds with the cord polygons of Figs. 111 (*b*), etc *

253. The resistance line is a broken line joining the points where the several resultants, forming the thrust line, cut the respective joints between the arch stones.

254. When the planes, by which the arch is supposed to be divided into segments, are vertical,* as in Fig. 114 (*b*), and, indeed, in most actual arches, the thrust and resistance lines, Fig 115, practically coincide; but if these planes are far from vertical, as in Fig. 115, the two lines separate, the resistance line being always the outer one.

Thus, in Fig. 115 (where the thrust line is shown solid, and the resistance line dotted), noticing where resultant *a* cuts joint A, where resultant *b* cuts joint B, etc., it will be seen that the two lines practically coincide as far as to joint C, where they begin to diverge.

* See Practical Considerations, ¶¶ 258, etc.

255. In ¶ 252 we assumed that the arch and its spandrel are divided into vertical segments, incapable (except in the arch ring) of exerting other than vertical pressures. The theoretical resistance line, thus obtained, may, especially in deep arches, pass from the thickness of the arch ring in places; so that, if no other forces were acting, the arch would open at such places; on the intrados when the resistance line cuts the extrados, and vice versa;

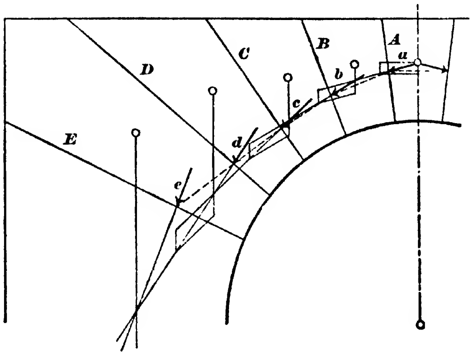

Fig. 115.

but such opening is usually prevented by other forces, such as the horizontal or inclined pressures of the spandrels. The actual resistance line is thus confined within the thickness of the arch ring. In general, the actual resistance line, Fig. 116, approaches the extrados at the crown, and the intrados at the haunches, so that the arch tends to sink at the crown (opening there on the intrados), and to rise at the haunches (opening there on the extrados), as shown.

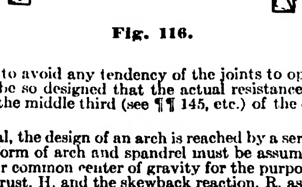

Fig. 116.

256. In order to avoid any tendency of the joints to open at either side, the arch should be so designed that the actual resistance line shall everywhere be within the middle third (see ¶¶ 145, etc.) of the depth of the arch ring.

257. In general, the design of an arch is reached by a series of approximations. Thus, a form of arch and spandrel must be assumed in advance, in order to find their common center of gravity for the purpose of determining the horizontal thrust, H, and the skewback reaction, R, as in ¶ 252; and, if it is afterward found necessary to modify the form first assumed, in order to satisfy the requirements of ¶ 256, or for other reasons, we may have to recompute H and R, again modifying the design, and so on.

Practical Considerations.

258. While the theoretical thrust and resistance lines, based upon the foregoing assumptions, are easily found, much uncertainty exists as to the positions of the actual thrust and resistance lines in a masonry arch.

259. *In the first place, we do not know through what points in the crown and skewback, respectively, the resultants, H and R, pass.*

260. Again, we have assumed that the loads on the arch, like those on the cord, Figs. 111 to 113, are incapable of acting otherwise than vertically; whereas the spandrel walls and filling, which form a large portion of the load on a masonry arch, may offer resistances acting in other directions. If the loading were a liquid, like water, its pressures upon the arch ring would be radial, like those of the particles of steam, in a boiler, upon the boiler tubes; and this condition is probably more or less closely approximated in the case of a loading of clean dry sand; and, less closely, in the case of earth filling. Hence, although the determination of the theoretical thrust and resistance lines in an arch is facilitated by the assumption that the arch is correctly represented by the inverted cord, the distinction between the two cases must be borne in mind when drawing practical conclusions from the lines so found.

261. Thus, in many cases, the theoretical thrust and resistance lines cut the intrados or the extrados in places, thus passing entirely out of the arch ring; so that this would inevitably fall (see ¶ 255), were it not for horizontal or inclined resistances exerted by the upper parts of the abutments through the spandrel walls and filling

262. Hence, in order to determine the actual resistance line, we should not only have to know through what points, in crown and in skewback respectively, the resultants, H and R, pass, but we should also have to ascertain and take into account the possible horizontal and inclined resistances of the spandrel walls and filling. But, as this is ordinarily impracticable, we content ourselves either with determining the theoretical thrust and resistance lines, as directed above, and then estimating, as well as may be, the resistances of the spandrels, or with reasoning by analogy from the behavior of actual structures. See Stone Bridges

263. If the inverted cord correctly represented the actual thrust line in a masonry arch, the arch stones, in elliptic or in deep segmental arches, would have to be made inordinately deep, in order that the resistance line should nowhere leave the middle third of their depth (see ¶¶ 145, etc.); and it might therefore appear rational to make the profile of the arch correspond approximately with the thrust line, which usually approaches a parabola. But, owing to the spandrel resistances, the actual thrust line, even in semicircular arches, probably seldom greatly oversteps the middle third.

264. With a wall or a deep continuous filling, over an arch, if the arch were to settle, or were to be removed, the wall and the filling above it would form an arch, as indicated by the broken lines in Fig 117; and only that portion

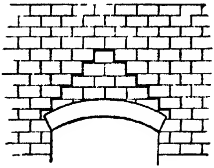

Fig. 117.

below this arch would fall out. Hence, only this portion can properly be regarded as pressing upon the arch.

265. Neglecting the strength of the mortar, the inclination of each joint between two arch stones must of course be such that the angle, between the thrust, at any joint, and a normal to that joint, shall be less than the angle of friction See ¶¶ 183, 184.

266. It is often the case that the spandrels or the spandrel filling are of less specific gravity than the arch ring. In such cases, in order to facilitate the finding of the lines of gravity of the segments, we may, before dividing the half-arch and its spandrels into vertical segments (¶ 252), consider the lighter structure of the spandrels as being reduced to an equivalent depth of material having equal specific gravity with the arch. The areas of the several segments, as seen in profile, and as thus reduced, may then be taken as representing their weights. Thus, in Fig. 118, where *t t t* represents the

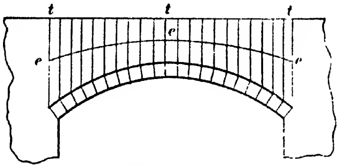

Fig. 118.

top of the spandrels, the curved line *e e e* represents the top of a filling of equal weight per foot run with the spandrels, but of equal specific gravity with the arch ring. When, as in Fig. 119, the spandrels consist of a series of transverse arches, we may assume that the main arch carries a series of loads concentrated at the piers of these transverse arches.

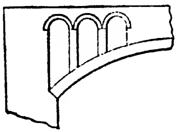

Fig. 119.

The Masonry Dam.

267. A dam must be secure against sliding, on its base or on any plane within the body of the dam, against overturning, and against crushing of the material at any point and consequent opening of a seam at either face of the dam.

268. The dam will be secure against sliding if the resultant of all the pressures, upon any surface, forms, with a normal to that surface, an angle less than the angle of friction of the surface. See ¶¶ 183, etc. In practice, the base of the dam is let well down into the rock foundation, as indicated in Fig. 122 (*a*), and continuity of joints is avoided by making all the stones break joints. The angle of friction thus becomes, in effect, 90°, and sliding cannot occur without shearing the stones themselves.

269. If the material is sufficiently strong to resist crushing, under the maximum unit stresses brought upon it, and if the resultant of all the forces acting upon any section falls within the body of the dam, the dam will be secure against overturning. But see ¶ 270.

270. For a given total pressure upon any section, the maximum unit pressure in the section would be least when the resultant cut the middle point of the section. See Center of Pressure, ¶¶ 133, etc. It is generally impracticable to secure this; but the dam must be so designed that, under the maximum unit pressure, the given material shall not be taxed beyond its safe crushing strength. If this is done, and if, under all conditions, the center of pressure is kept within the middle third (see ¶ 150) of each horizontal section throughout the dam, there will be no tendency to open on either face of the dam.

271. Let Fig. 120 represent a stone block, resting upon a solid foundation and intended to sustain the pressure, p, of quiet water on one side. Through the center of gravity, g, of the block, draw o'N vertically, to represent the weight, W, of the block. Then the point, s, where o' N meets the foundation, is the center of pressure for the block alone, *i e*, when the water is removed.

272. Let h be the depth of water back of the block, and let the block be one foot in length, measured normally to the paper. Then the amount, in pounds, of the water pressure, against the vertical back, $a\,b$, is $p = 62.5\,h \times \frac{1}{2}\,h$, and its center of pressure is at a depth, $d = \frac{2}{3}\,h$, below the water surface.

273. Combining p with W (¶ 35) we obtain R as their resultant, and r as the center of pressure upon the foundation when the block is sustaining the water pressure.

274. Let Fig. 121 represent several such blocks superposed Let

g_1 = cen of grav, p_1 = cen of water pres, for block 1;
g_2 = " " " p_2 = " " " " " blocks 1 and 2 combined;
g_3 = " " " p_3 = " " " " " " 1, 2, and 3 combined,
etc

Then, finding r_1 and s_1, r_2 and s_2, r_3 and s_3, etc , for joints 1–2, 2–3, 3–4, etc , as before, we have the points r_1, r_2, r_3, etc , in the resistance line for full dam, and the points s_1, s_2, s_3, etc , in the resistance line for empty dam.

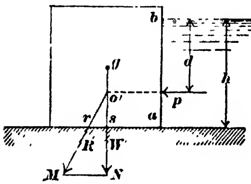

Fig. 120.

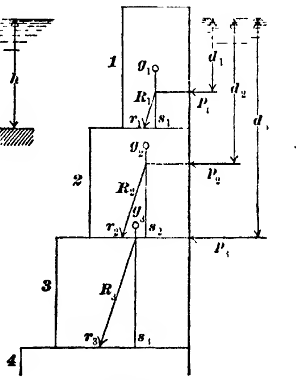

Fig. 121.

275. In Fig. 122 (a) the curves, $u\,u$ and $d\,d$, indicate the up-stream and down-stream limits, respectively, of the middle third of the plane separating each two blocks, assuming the profile with vertical back; and the points $r_1 \ldots r_7$ and $s_1 \ldots s_7$ are points in the corresponding resistance lines for full dam and for empty dam respectively.

276. While theory would require the cross-section of the dam to terminate in a sharp angle at the top, it is, of course, always made heavier in practice, as indicated in Fig. 122 (a).

277. For joint 2–3 we may suppose that block 2 had at first been designed rectangular, as shown by dotted line $c\,a$ (Fig. 122 (c), showing blocks 1 and 2 enlarged); but this makes the center of pressure, r', for the full dam, fall beyond the middle third of the narrow base, $a\,b$. We therefore try the trapezoidal shape $c\,i\,b$, with its wider base, $i\,b$, and find that, with this, the center of pressure, r_2, although further down-stream than before, falls within the middle third of said wider base. The remainder of the profile is determined by similar trials.

278. Graphic Method. Suppose the cross-section to be divided, by horizontal sections, into numerous blocks, 1, 2, 3, 4, etc., of a depth approximately = the top width of the dam. In Fig. 122 (*b*), draw 0–1, 1–2, 2–3, 3–4, etc., vertically, to represent, by scale, the weights of the several blocks, respectively, and 0–1′, 1′–2′, 2′–3′, 3′–4′, etc., horizontally, to represent the water pressures against said blocks respectively; and draw 1′–1, 2′–2, 3′–3, 4′–4, etc., representing, in amount and in direction, the total inclined pressures upon joints 1–2, 2–3, 3–4, etc., and upon the base, respectively. Thus, 2′–2 represents the resultant of the water pressure (see Hydrostatics) upon blocks 1 and 2, and the combined weight of those blocks. From the points, o_1, o_2, etc., Fig. 122 (*c*), where these two forces meet in each case, draw $o_1\ r_1$, $o_2\ r_2$, etc., parallel respectively to 1′–1, 2′–2, etc., Fig. 122 (*b*), to the corresponding joint. We thus obtain points, $r_1 \ldots r_6$, in the resistance line for the case where the dam is filled to the assumed depth.

The foregoing refers to the diagram for a dam already completed or designed. In designing *de novo*, we of course begin at the top, and lay off the lines 0–1, 0–1′ and 1′–1 in Fig. (*b*) for the first block; then lines 1–2, 1′–2′ and 2′–2, for the second block, and so on; making necessary changes, as in ¶ 277.

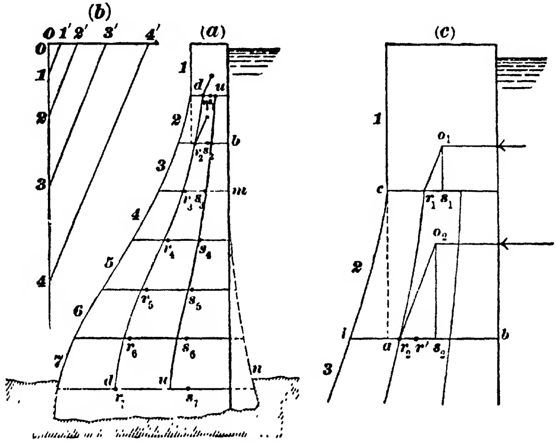

Fig. 122.

279. In order that the resistance line, $r_1 \ldots r_6$, for the full dam, may be brought well within the middle third, it may sometimes be necessary to adopt a somewhat unwieldy cross-section; but, in view of the imminent danger involved in the smallest opening on the up-stream side of the dam, (see ¶ 281), it is well here to err on the safe side.

280. As this process is carried further down, the angle formed between the down-stream face and the vertical becomes considerable; and the middle third, in each of the lower joints, is thus brought further down-stream. The centers of pressure, $s_1 \ldots s_6$, for empty dam, may then fall beyond the middle third, on the up-stream side, as indicated at joints 5–6 and 6–7. To obviate this, the up-stream face is sometimes given a curved profile, as at $m\ n$.

Practical Considerations.

281. The assumption of ideal conditions is particularly dangerous in the case of masonry dams. Thus, any compression of the material at the down-stream face may open seams on the up-stream face; and water, entering these seams, will exert a wedge-like action, shifting the resistance line further down-stream, thus still further increasing the tendency to crushing on the down-stream face and to opening on the up-stream face. Again, if any relatively smooth joints have been left, the water, thus penetrating into or under the dam, increases the tendency to slide, not only by diminishing the effective weight of the upper portions, but also by acting as a lubricant upon the seam where it penetrates.

It has been suggested that failures of dams may have been occasioned, in part at least, by vacuum, formed in front of the down-stream face, by the action of the sheet of water falling in front of that face.

282. Theoretically, the deflections of arches, dams and other structures composed of blocks, may be found by means of the formulas in ¶¶ 162–167 of Trusses; but, owing to uncertainty as to the values of the moduli of elasticity, E, of building stones and of mortar, and to the relative inaccuracy of finish in masonry work, the formulas are of but little practical value in such cases.

THE SCREW.

283. The screw is a spiral inclined plane. The force (or "power") describes a spiral, at the end of a lever arm, while the resistance (or "weight") moves along the axis of the screw. During the time in which the force makes one revolution, the resistance traverses the "pitch," or distance between the centers of two adjacent threads.

284. Hence, if P = power, w = weight, d = pitch, l = lever arm, v = rectilinear velocity of weight, and V = linear (circular) velocity of power, we have, theoretically:*

$$\frac{w}{P} = \frac{V}{v} = \frac{2\,\pi\,l}{d}.$$

* Neglecting friction, which, however, very greatly modifies the result.

FORCES ACTING UPON BEAMS AND TRUSSES.

Conditions of Equilibrium.

285. In beams and trusses, for equilibrium, it is necessary and sufficient that the resisting forces, exerted by the material of the structure, and the moments of those forces, shall balance the external or destructive forces and their moments. We here discuss chiefly the destructive forces. For the resisting forces, see Stresses, under Trusses, and Beams or Transverse Strength, under Strength of Materials.

286. The destructive forces are (1) the loads upon the structure, including its own weight, "live" or moving loads, wind, etc., and (2) the reactions of the supports. We shall here discuss the action of vertical loads only, including (*a*) the dead load, or the weight of the structure itself, together with the roadway, etc., and (*b*) the live, moving or extraneous load of vehicles, trains, persons, etc. The action of horizontal loads (wind, centrifugal force, etc.) is governed by similar laws, and is discussed under Stresses, in Trusses.

287. Let Fig. 123 (*a*) represent a cantilever, resting upon a support, *b*, and bearing a load, W, at its outer end, *a*. The cantilever is prevented from turning about *b*, by the tension, T, of a horizontal chain, and by the compression, C, in a horizontal strut.* Neglecting the weight of the cantilever

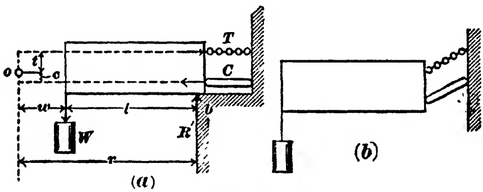

Fig. 123.

itself, the cantilever is acted upon by four external forces, forming two couples; one couple consisting of two vertical forces—viz., the load, W, and the reaction, R', of the support; the other couple consisting of two horizontal forces—viz., the tension, T, near the top, and the compression, C, near the bottom. Were it not for the reaction, R', of the support, *b*, the load, W, would pull the cantilever downward, as indicated in Fig. 123 (*b*).

288. In Fig. 123 (*a*) we have:

Algebraic sum of vertical forces $= R' - W = 0$;
" " " horizontal " $= T - C = 0$;
" " " moments, about any point, as *o*,

$$W.w - R'.r + T.t + C.c = 0.$$

---

* In Figs. 123 to 127, inclusive, and Figs. 132 and 133, showing cantilevers, beams and part beams, acted upon by loads, by reactions, by pulls of chains and by pushes of struts, the arrows denote forces acting *upon the cantilever or beam or upon its segments*, and not forces acting upon the load, the supports, or the connecting chains or struts. Thus, the tension in a chain tends to *draw together* the two bodies which it connects. Hence, in these cases, the corresponding arrows point *toward each other*. On the other hand, the compression in a strut tends to *separate* the two bodies between which it acts. Hence its two arrows point *away from each other*.

289. If, as in Fig. 124, the horizontal forces are exerted at the end farthest from the support, and at the same distance apart as before, their amounts and senses must remain respectively the same as before; but we now have compression, C, at the top, and tension, T, below. Or, if Fig. 123 be inverted, R′ acts as the load, and W as the upward reaction; and we have, as in Fig. 124, compression, C, at top, and tension, T, below. Thus, Fig. 124 is practically Fig. 123 inverted.

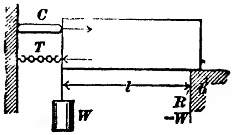

Fig. 124.

290. The condition described in ¶ 289. Fig. 124, represents also the condition in each segment, A, B, of a beam, Figs. 125 (*a*) and (*b*) or Figs. 126 (*a*) and (*b*), supported at both ends and bearing a concentrated load, W + W, Fig. 125, or W + *w*, Fig. 126.

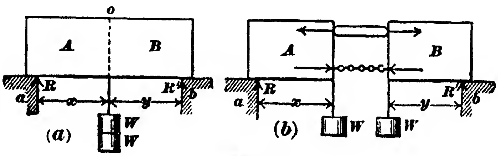

Fig. 125.

291. Suppose the beam, Fig. 125 (*a*) or Fig. 126 (*a*), to be divided into two cantilevers, or part beams, as in Fig. 125 (*b*) or Fig. 126 (*b*); each part sustaining, at its end, a part of the original load. (See ¶ 292.) The stresses in the strut and chain, Figs. (*b*), take the place of stresses in the material (situated in the dotted line) of the truss or beam, Figs. (*a*). In a truss, these forces are exerted by the chords: in a beam, by the particles or fibers throughout the section.

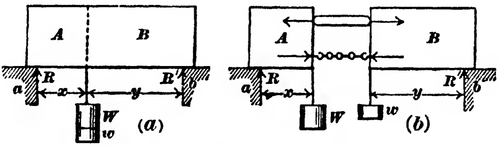

Fig. 126.

292. If, as in Fig. 125 (*a*), the load is at the center of the span, the spans, x and y, of the cantilevers, Fig. 125 (*b*), are equal, as are also the loads, W = W, carried by them. But if, as in Fig. 126 (*a*), the load, W + w, on the beam, is not at the center of the span, the partial loads, W and w, supposed to be supported at the ends of the two cantilevers, or part beams, respectively, Fig. 126 (*b*), are unequal, and inversely proportional to their leverages about their respective supports. Hence, the moments of the two opposite couples are equal. The reaction of each support is equal to the weight carried by the cantilever resting upon it.

End Reactions.

293. In a cantilever, Fig. 127, there is but one vertical support; the reaction, R′, of that support, is = the sum of all the loads, including the weight of the cantilever itself; and the reaction due to each partial load is = such partial load. Thus, if B = weight of cantilever,

$$R' = W + w + B.$$

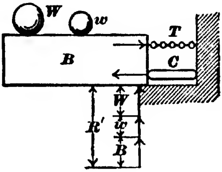

Fig. 127.

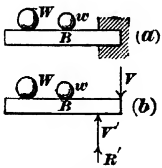

Fig. 128.

294. The reaction, R′, must not be confounded with other vertical forces. Thus, a cantilever is often supported as in Fig. 128 (*a*). The couple, composed of two horizontal forces, T and C, Fig. 127, is then replaced by a couple composed of two vertical forces, V and V′, Fig. 128 (*b*); one of which, V′, coincides with the reaction, R′. Here, R′ + V′, acting upward, is the anti-resultant of W, *w*, B and V, acting downward.

295. In a beam, Fig. 129, the sum of the two end reactions is = the sum of all the loads, including the weight of the beam itself.

296. The reaction, R, of the left support, *a*, Fig. 129, due to the load, W, alone, is $R = W \cdot \frac{y}{l}$ (see ¶ 17), and the reaction, R′, of the right support, *b*, is $= W - R = W \cdot \frac{x}{l}$. If the load is central, $\frac{x}{l} = \frac{y}{l} = \frac{1}{2}$, and $R = R' = \frac{W}{2}$.

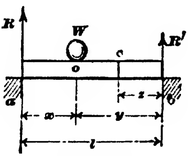

Fig. 129.

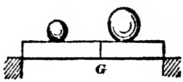

Fig. 130.

297. Graphically, Fig. 156, suppose a concentrated load, W (not shown), to be placed on the beam at any point, as *c*. Draw *a′ a″* and *b′ b″*, vertical and each = W. Join *a″ b′*; also join *a′ b″*, and draw *g h* vertically through *c′*. Then the ordinate, *c′ g*, to the upper line, *a″ b′*, and the ordinate, *c′ h*, to the lower line, *a′ b″*, give the left and the right end reactions, R and R′, respectively.

298. Where, as in Fig. 130, there are two or more loads (in which the weight of the beam may or may not be included), the reactions due to each load may be separately obtained, the sums of these reactions giving the total reactions; or, the common center of gravity, G, of all the loads may first be found (see ¶¶ 125, etc.), and then the reactions found as for a single load, W, Fig. 129; the combined weight of the loads, whose center of gravity is at G, being supposed concentrated there.

299. In a beam, Fig. 131, under a load, W, uniformly distributed over any part of the span, let G be the center of gravity of the load, and let x and y be the segments of the span, l, to the left and right of G respectively. Then, neglecting the weight of the beam, $R = W\frac{y}{l}$; and $R' = W - R = W\frac{x}{l}$.

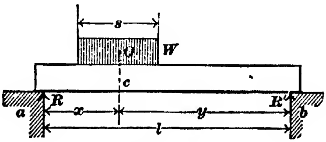

Fig. 131.

300. If the load is uniformly distributed over the entire span, its center of gravity is at the center of the span, and we have:

$$\frac{x}{l} = \frac{y}{l} = \frac{1}{2}; \text{ and } R = R' = \frac{W}{2}.$$

Moments and Shears.

301. In order to determine what internal stresses are required, at any point in the span, to maintain equilibrium, we may suppose the cantilever or beam to be cut in two by a section, *c c*, Fig. 132 or Fig. 133, at such point, and inquire what forces must be applied, in the section, in order to maintain equilibrium and hold in position the two segments, E and F, into which the section, *c c*, divides the span, Fig. 132, or that part of the span between the load and a support, Fig. 133. The forces, so ascertained, are evidently equivalent to those actually exerted, for the same purpose, by the material of the beam itself.

302. In Figs. 132 and 133, moments of loads and of reactions, or *external* or bending moments, are indicated by arrows *below* the cantilever and beam respectively; while the resisting moments of the *internal* forces are indicated by arrows *within* the body of the cantilever or beam respectively.

303. In the cantilever, Fig. 132, the load, w, = 4 lbs., distant 6 ft. from the section, *c c*, produces there a left-hand or negative moment of $6\,w = 6 \times 4 = 24$ ft.-lbs. Hence, for equilibrium, the horizontal strut and chain, at *c c*, must exert a right-hand or positive resisting moment of 24 ft.-lbs; and, being 2 ft. apart, they must exert a tension, T, and compression, C, of $\frac{24}{2} = 12$ lbs. each. At the support, moment of load $= 9\,w = 9 \times 4 = 36$ ft.-lbs.; and $T' = C' = \frac{36}{2} = 18$ lbs.

304. But, considering only the forces thus far discussed, we should find the right segment, F, acted upon, at *c c*, by a left-hand couple, $= d \times T = d \times C = 2 \times 12 = 24$ ft.-lbs.; and, at the support, by a right-hand couple, $= d \times T' = d \times C' = 2 \times 18 = 36$ ft.-lbs. In other words, there would be an unbalanced excess of right-hand moment, $= 36 - 24 = 3\,R' = 3 \times 4 = 12$ ft.-lbs., acting upon F. F also receives, at the support, the upward reaction, R', = 4 lbs., of that support. Similarly, the couple, $d \times T = d \times C$, at *c c*, exerts, upon the left segment, E, an apparently unbalanced right-hand moment of $2 \times 12 = 6\,w = 6 \times 4 = 24$ ft.-lbs., and E receives, from the load, w, a downward pull = 4 lbs.

305. For equilibrium, therefore, the vertical chain at *c c* must exert a tension $= S = w = R' = 4$ lbs., pulling F downward, and E upward. The downward tension, $-S$, acting on F at *c c*, forms, with the reaction, R', of the support, a left-hand couple $= 3\,R' = 3 \times 4 = 12$ ft.-lbs., balancing the excess of right-hand moment acting upon F; while the upward tension, $+S$, acting on E at *c c*, forms, with the weight, w, a left-hand couple, $= 6\,w = 6 \times 4 = 24$ ft.-lbs., balancing the excess of right-hand mom. acting on E

306. Similarly, if we suppose the cantilever cut through by a section at any other point, we shall find that a vertical force, = S = w = R′, acting upward upon the left segment and downward upon the right segment, is required in order to maintain equilibrium and to transmit the load, w, to the support, so that the two segments may act unitedly as a single cantilever. This force, S, is called a shear. See ¶¶ 325, etc. Without it, section E would fall, as in Fig. 123 (b).

307. In the beam, Fig. 133, the total load is 16 lbs.; and, its distances, 3 ft. and 9 ft., from the left and from the right support respectively, being as 1 to 3, the end reactions (¶¶ 293, etc.) are as 3 to 1; or R = 16 × ¾ = 12 lbs.; R′ = 16 × ¼ = 4 lbs. We therefore regard the beam as being cut by a section at the load (as well as at c c), and the total load of 16 lbs. as divided into two portions; one, W = R = 12 lbs., attached to the end segment, M; and the other, w = R′ = 4 lbs., supported by the middle segment, E. Here, as in Fig. 132, segments E and F together form a cantilever, 9 ft. long, loaded with a weight, w, of 4 lbs., at its end; but,

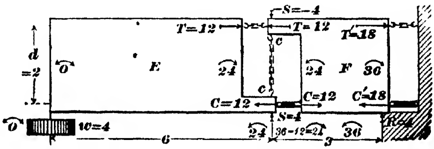

Fig. 132.

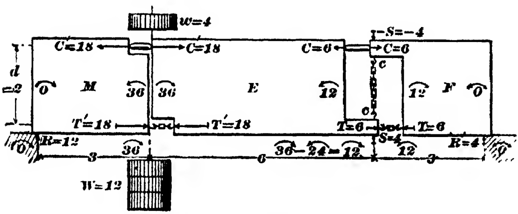

Fig. 133.

in Fig. 133, the horizontal resisting forces, T′ and C′, by which the entire cantilever (E + F) is upheld, are exerted, not at the support, as in Fig. 132, but at the end farthest from the support.

308. We have, therefore, in Fig. 133, positive (clockwise) and negative (counterclockwise) moments, as follows, acting upon E, about the lower end of c c:

$$d\,C' - 6\,w - d\,C = 2 \times 18 - 6 \times 4 - 2 \times 6 = 0.$$

Here, $d\,C' - 6\,w$, = 36 − 24 = 12, is bending moment, and $-\,d\,C$, = − 12, is resisting moment.

We have, also, in c c, shear, S = w = R′ = 4 lbs.

309. In Fig. 132 or in Fig. 133, considering the segment extending from the load to either support (in Fig. 132 there is but one such segment), it will be seen that, at the free end of any such segment, the horizontal stresses are zero, and that they increase uniformly to a maximum at the other end of the segment. Thus, in Fig. 132, they increase uniformly from 0, at the loaded or free end, to 18 lbs., at the support; while, in Fig. 133, they increase uniformly from 0, at each support, or free end, to 18 lbs., at the load.

Moments in Cantilevers. See also pp 437 &c.

310. In a cantilever, Fig. 134, each load exerts, about any point between itself and the support, a moment = its weight × the horizontal distance of its center of gravity from such point; and the total moment, at any point is the sum of the moments of the several loads about that point. Thus neglecting the weight of the cantilever itself, we have:

about b, mom = $A\ x + B\ y$; about d, mom = $A\ z$;
about c, mom = $A\ m + B\ n$; about A, or any point beyond A, mom = 0

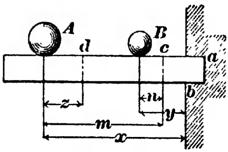

Fig. 134.

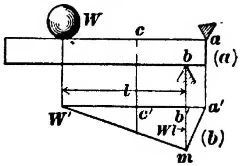

Fig. 135.

311. In a cantilever, Fig 135, the maximum leverage of any load, W, is evidently its distance, l, from the support, b. Hence, the maximum bending moment of any load upon a cantilever is at the support, and is = $W\ l$. From this max, the mom diminishes uniformly to 0, at the load and at a.

In Fig. 134, the end, $b\ a$, is uniformly loaded, and the diminution of mom, betw b and a, follows the ordinates of a parabola, as in $m\ k'$, Fig. 137.

311 a. In cantilevers and beams, Figs 129, 134, *clockwise* moments of forces, to the *left* of a given point, c, about that point, are considered *positive*, and vice versa. *Positive* moments *extend* the *lower* and *compress* the *upper* fibers, and vice versa.

312. In Fig. 135 (b), (cantilever with a single load, W,) draw $b'\ m$, = max mom by scale, and join $m\ W'$ and $m\ a'$. Then, for any point, c,

moment = ordinate at c' to line $m\ W'$.

313. In a cantilever, Fig. 136 (a), with two or more concentrated loads, W and w, let

$b'\ m$, Fig. 136 (b), = moment of W, at the support;
$b'\ m'$, Fig. 136 (b), = moment of w, at the support.

Then, for both loads, W and w, neglecting the weight of the beam,
at d, moment = moment of W alone, = ordinate at d';
at c, moment = sum of moments of W and w,
= sum of two ordinates, $c'\ n$ and $c'\ n'$, at c'.

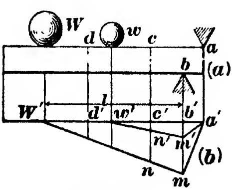

Fig. 136.

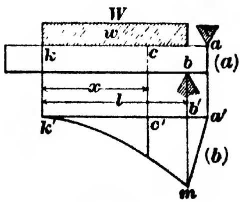

Fig. 137.

314. In a cantilever, Fig. 137 (a), under a load, W, uniformly distributed over a length, l, beginning at the support, b, the maximum moment, at the support, b, is = $W\ l/2$.

In Fig. 137 (*b*), make $b'\,m$ = said max moment, and draw a semi-parabola $m\,k'$, with apex at k'. Then, at any other section, c, the moment is represented by the ordinate, c', of said parabola, and is $= w \cdot \frac{x}{2}$, where w = the weight of that portion of W beyond c, and x = the length of that portion.

At k, or at any point beyond k, moment = 0.

315. In Fig. 138, neglecting the weight of the cantilever itself, let W represent the weight of the whole load, and w, that of the shaded portion, concentrated at their respective centers of gravity, G and g. Then,

about b, moment $= W \cdot x$;
" c, " $= W \cdot y$,
" d, " $= w \cdot v$;
" k, or any point beyond k, moment = 0.

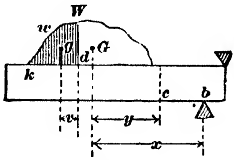

Fig. 138.

Moments in Beams.

316. In a beam, Fig. 129, the upward reaction of each abutment exerts, about any point, a moment = reaction × distance of support from such point; but any load, between such point and the support, exerts a contrary moment = load × distance of load from such point. Thus,

about c, moment $= R'\ z = R\,(l - z) - W\,(y - z)$.

At each support, the moment is 0

317. In a beam, Fig. 129, carrying a single concentrated load, W, the moment, $R'.z$, at any point, c, is $= R'z = W\frac{x}{l} \cdot z - R\,(l - z) - W\,(y - z)$ $= W \cdot \frac{y}{l}\,(l - z) - W\,(y - z)$. At a point, as c, not under the load, the moment, $R'z$, is evidently less than the moment, $R'.y$, about the point, o, under the load. In other words, the maximum moment is at the point, o, under the load.

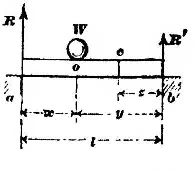

Fig. 129 (repeated).

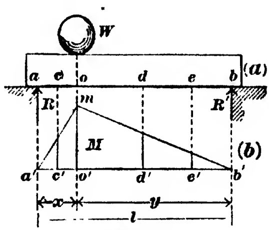

Fig. 139.

318. From the point, o', Fig. 139 (*b*), corresponding to the point, o, Fig. (*a*), where the load is applied, erect an ordinate, $o'\,m$, equal by scale to the (maximum) moment, $= R' \cdot y = R \cdot x$, at that point. Join $a'm\,b'$. Then the ordinate to $a'm$, or to $m\,b'$, at any point, c', d', e', etc., represents by scale the moment at the corresponding point, c, d, e, etc., in the span.

319. When the load, W, is at the center of the span, l, Fig. 140, each end reaction is $= \frac{W}{2}$. Hence, the moment s', at any point, s, distant y from a support, as b, is

$$\text{moment} = \frac{W}{2} \cdot y.$$

At the center of the span (*i. e.*, at the point under the central load, W) we have:

$$\text{maximum moment, M,} = \frac{W}{2} \cdot \frac{l}{2} = \frac{W.l}{4}.$$

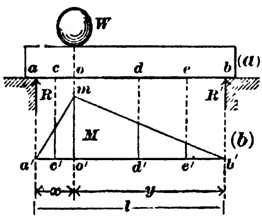

Fig. 139 (repeated).

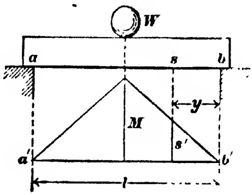

Fig. 140.

In order that the maximum moment (at o, Fig. 139) due to an eccentric load, W, may be equal to the maximum moment (at center of span, l) due to a given center load, C, we must have

$$W \frac{x}{l} . y = C . \frac{l}{4}; \text{ or } W = C\frac{l}{4} . \frac{l}{xy} = C\frac{\left(\frac{l}{2}\right)^2}{xy}$$

320. When there are two or more concentrated loads, c, d, e, Fig 141, treat each load as in Fig 139, making each short ordinate, m, m', m'', represent the maximum moment of its single load, c, d or e, alone. Make the long ordinates, M, M′ and M″ = the sums of the separate moments, as measured at c', at d', and at e', respectively. Then the ordinate to a' M M′ M″ b', at any point, represents the total moment at that point, due to the several loads combined.

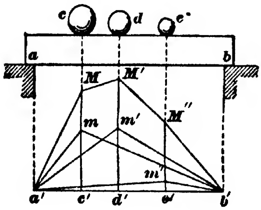

Fig. 141.

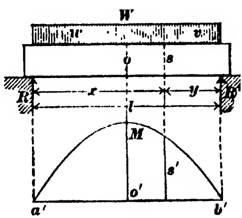

Fig. 142.

321. In a beam, Fig. 142, under a uniform load, W, covering the span, l, the maximum moment is at the center of the span, and is

$$\text{moment} = R.\frac{l}{2} - \frac{W}{2}.\frac{l}{4} = \frac{W}{2}.\frac{l}{2} - \frac{W}{2}.\frac{l}{4} = \frac{W}{2}.\frac{l}{4} = \frac{W.l}{8}.$$

Make $o'M$, by scale, = the maximum moment; and draw the parabola, a' M b', with vertex at M. Then the moment, at any section, as s, is represented by the corresponding ordinate, s', to that parabola.

Let w and v = the portions of W to the left and right of s, respectively. Then, moment at $s = \frac{w}{2} y * = \frac{v}{2} x * = \frac{1}{2}$ moment due to whole load, W, concentrated at s.*

At either support, moment = 0.

In Fig. 131, at a point, c, under the center of gravity of a load, W, uniformly distributed over a portion, s, of the span, neglecting the weight of the beam,

$$\text{moment} = R.x - \frac{W}{2} \cdot \frac{s}{4} = R.x - \frac{W.s}{8} = R'.y - \frac{W.s}{8}.$$

322. Let W = the total load, whether concentrated or uniform, and let l = the span. Then the maximum moment, M, is as given below:

Cantilever	Load, W, at end	M at support	$M = W\,l$;
"	" " uniform.	" " "	$M = \frac{W\,l}{2}$;
Supported beam †	" " at center.	" at center	$M = \frac{W\,l}{4}$;
" "	" " uniform.	" " "	$M = \frac{W\,l}{8}$;
Fixed beam.‡	" " at center.	" " " or support	$M = \frac{W\,l}{8}$,
" "	" " uniform.	" " support	$M = \frac{W\,l}{12}$.

323. In the inclined beam, Fig 143, the inclined distances may be used, instead of the horizontal distances, in finding the reactions. Thus,

$$\text{reaction } R' = W \cdot \frac{x}{l} = W \cdot \frac{x'}{l'}.$$

But, in finding moments of vertical forces, we must of course use the horizontal, not the inclined, distances. Thus, at c, moment $R'c$; not $R'c'$.

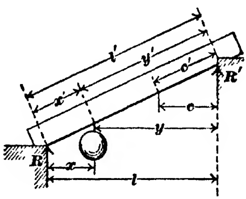

Fig. 143.

* Moment at $s = R'\,y - v\,\frac{y}{2} = \frac{W}{2}\,y - \frac{v}{2}\,y = \frac{W - v}{2}\,y = \frac{w}{2}\,y$
$= R\,x - w\,\frac{x}{2} = \frac{W}{2}\,x - \frac{w}{2}\,x = \frac{W - w}{2}\,x = \frac{v}{2}\,x.$

With W concentrated at s,

$$\text{moment at } s = W\,\frac{x}{l}\,y = w\,y = W\,\frac{y}{l}\,x = v\,x.$$

† Beam supported at each end, but not fixed.

‡ Beam fixed at each end.

324. In curved beams, the same principles apply as in straight beams. Thus, Fig. 144, at *s*, moment = W . *l*. Again, in Fig. 145 (*a*), reaction R' $= \frac{W . x}{l}$, and at *s*, moment = R' . *y*. Or, as in Fig. 145 (*b*), from *o*, where the load is applied, draw *o a* and *o b*, to the two supports respectively, and, by means of the force parallelogram, find the components, *p* and *q*, of W. Then, at *s*,

moment = *p* . *n*.

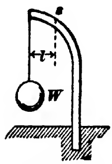

Fig. 144.

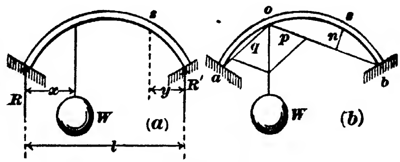

Fig. 145.

Shear.

325. In the beam, *a b*, Fig 146 (*a*), consider the segments, *a c* and *c b*, to the left and to the right respectively of the plane *n n*. Besides the horizontal forces acting across the plane *n n*, we have seen (¶ 305) that we require also, for equilibrium, a vertical force, = the left end reaction, R, acting downward upon the left segment, *a c*, and forming a couple with R; and, at the same time, acting upward on the right segment, *c b*, being = the load, W, minus the right end reaction, R'. This force is called the shear, S, in the section *n n*. It may be regarded as the transmission of the vertical forces from loads to supports or vice versa.

326. The two segments, *a c* and *c b*, thus tend to slide vertically past each other, the right segment, *c b*, tending downward, owing to the preponderance of the load, W, over the right end reaction, R'; and this tendency is resisted by the shear, S, which is = the left end reaction, R. The same tendency exists uniformly between W and *a*, and is resisted throughout by a shear = S = R

327. Between the load, W, and the right support, *b*, also, a uniform shear exists; but here the shear, S', is = the right end reaction, R', = R — W; and, whereas the shear, S, to the *left* of the load was *right*-handed or *clockwise* (the portion to the *right* of any section, *n n*, receiving the *downward* force), and is called *positive*, or +, the shear on the *right* of the load is *left*-handed or *counterclockwise* (the portion to the *left* of any section receiving the *downward* force), and is called *negative*, or —.

328. The shears, S and S', to the left and to the right of the load, W, are represented by the diagrams in Fig. 146 (*b*); that, S, on the left of the load being drawn *above* the zero line, *a' b'*, to indicate a *positive* shear, and vice versa.

329. Comparing Figs 146, 147 and 148, notice that, between the left support, *a*, and the load, W, Fig. 146, we have positive shears, S = 90, Fig. 146, and *s* = 15, Fig 147; so that, in Fig. 148, where *both* loads, W and *w*, are placed upon the same beam, we have, between *a* and W, a total positive shear of S + *s* = 90 + 15 = 105. Between the right support, *b*, and the load, *w*, Fig. 147, we have negative shears, S' = — 30, Fig. 146, and *s'* = — 45, Fig 147; so that, in Fig 148, between *b* and *w*, we have a total negative shear = S' + *s'* = — 30 — 45 = — 75. But, between the points of application of W and of *w*, we have S' = — 30, Fig. 146, and *s* = + 15, Fig. 147; leaving, between W and *w*, Fig. 148, *s* + S' = 15 — 30 = — 15. If the total right end reaction, R' + *r'*, exceeds *w*, as we here suppose, the shear, at any point between the two loads, W and *w*, Fig. 148, is negative, as indicated; and vice versa.

330. In any section, the shear is = the reaction at either end, minus any loads between that end and the given section.

331. If, as in Fig. 149, the right end reaction, $R' + r'$, is = the load, w, then the left end reaction, $R + r$, is = the load, W; and there is no shear at any point between the two loads. In other words, if the beam be cut by a section at any point between W and w, horizontal forces alone will preserve equilibrium, no vertical forces being required, since the two segments have no tendency to slide vertically past each other.

332. A similar condition exists in any section where the sign of the shear changes from + to — or vice versa. Thus, if the beam be cut by a section immediately under W, Fig. 146 or 148, or under w, Fig. 147, horizontal forces equivalent to the fiber stresses in the beam, will suffice to preserve equilibrium, without a vertical force, or shear; there being no tendency of the two segments to slide past each other. Also, when, as in Fig. 149, under W and under w, the shear changes, in amount, from any value, on one side of a section, to 0, on the other side, the shear in the section itself is = 0.

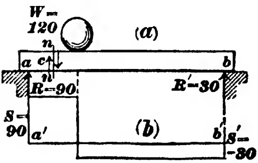

Fig. 146.

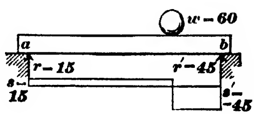

Fig. 147.

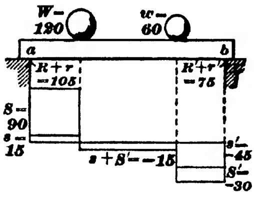

Fig. 148.

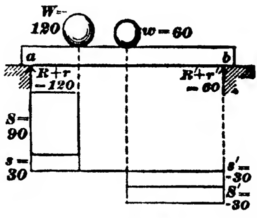

Fig. 149.

333. But in the section under w, Fig. 148, where the shear changes in amount, although not changing sign from + to — or vice versa, there is a shear = the *less* of the two shears on the opposite sides of the section, for this is the amount of the shear transferred through the section, or is the tendency of either segment to slide past the other.

334. With any number of loads, if that portion of the total load to the left of any section be called X, and that portion to the right of the same section be called Y, it will be found that the shear in the section is equal to the difference between that part of X which goes to the right support, b, and that part of Y which goes to the left support, a.

335. With a load, W, Fig. 150 (a), uniformly distributed over the entire span, the maximum shear, $= R = R' = \frac{W}{2}$, is at each support, a and b. The minimum shear, = 0, is at the center, c, of the span, which is also the point of maximum bending moment, see ¶ 321 and Fig. 142. At any point,

d, the shear is given by the corresponding ordinate, d', Fig 150 (b). See Relation between Moment and Shear, ¶¶ 359, etc.

336. With a load, W, uniformly distributed over any part y, of the span, Fig. 151 (a), find the end reactions, R and R', as in ¶ 299. Then

$$\begin{array}{lll} \text{between } a \text{ and } d, & \text{shear} & = S = R; \\ \quad '' \quad e \text{ and } b, & \quad '' & = S' = R'; \\ \text{at } c, & \quad '' & = 0. \end{array}$$

$$x = d\,c = y\cdot\frac{R}{W};\quad z = y - x = c\,e = y\cdot\frac{R'}{W}.$$

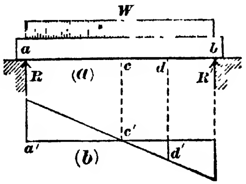

Fig. 150.

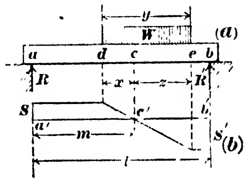

Fig. 151.

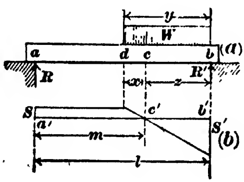

Fig. 152.

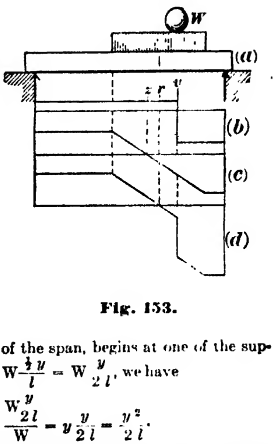

Fig. 153.

337. When the loaded portion, y, of the span, begins at one of the supports, b, Fig. 152 (a), then since $R = W\frac{\frac{1}{2}y}{l} = W\frac{y}{2\,l}$, we have

$$x = d\,c = y\cdot\frac{R}{W} = y\,\frac{W\frac{y}{2\,l}}{W} = y\,\frac{y}{2\,l} = \frac{y^2}{2\,l}.$$

338. When a concentrated load, W, Fig. 153, is added to a load uniformly distributed over the entire span, or over a part of it, each load produces the same shears as if it alone were upon the span. Those due to W are represented in Fig. 153 (b), while those due to the uniform load are represented in Fig. 153 (c). The resultant shear, due to both loads combined, is represented in Fig. 153 (d). Note that, between v and r, the addition of W, with its *positive* shear, *reduces* the *negative* shear due to the uniform load, and that, between r and z, the addition of W reverses the negative shear; also that it shifts the zero point from z to r.

For Continuous Beams, see Beams, under Strength of Materials.

Influence Diagrams.

339. The end reactions, due to a given load, and consequently the moments, shears and stresses, produced, at any given point in a span, by such load, vary as the position of the load, relatively to the supports, is changed. A diagram, Figs. 154 (*b*), 155 (*b*), 156 (*b*), showing the changes thus produced at any given point, is called an influence diagram, or influence line.*

Influence Diagram for Moments.

340. Thus, in Fig 154 (*b*), *a'Mb'* is the moment influence diagram for the point, *c*, under a single concentrated load, W.†

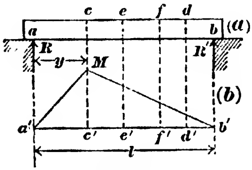

Fig. 154.

341. In Fig. 154, let l be the span, x the variable distance of the load, W,† from the right support, *b*, and y the constant distance, *a c*, of a given point, *c*, from the left support, *a*. Then, for any position of W, the left end reaction, R, is $= W \cdot \frac{x}{l}$, and the moment of that reaction about c, $= R \cdot y$, $= W \cdot \frac{x}{l} \cdot y$. The right end reaction is $R' = W \frac{l - x}{l}$, and its moment, about c, is $R' \, (l - y) = W \frac{l - x}{l} \, (l - y)$.

So long as W is between *b* and *c*, the moment at *c* is $= R \cdot y = W \cdot \frac{x}{l} \cdot y$.

342. Since W, y and l are constant, the moment, at *c*, while W is between *b* and *c*, is proportional to the variable distance, x, of the load from *b*. It therefore increases uniformly, from 0, when W is at *b*, to its maximum value, M, when W is at *c*. See ¶ 317. Hence, if the ordinate, *c'* M, be made equal, by scale, to the maximum moment, M, then the moment, at *c*, for any position, *d*, *e* or *f*, of W, between *c* and *b*, is given by the corresponding ordinate, *d'*, *e'* or *f'*, to the line *b'* M. Similarly, the moments, at *c*, for any positions of W between *c* and *a*, are given by the ordinates to the line *a'* M.

343. For the moment, at *c*, for any number of loads, in any positions, find the moment, at *c*, for each load separately, as above, and take their sum.

344. It is customary to construct the moment influence diagram for the moments of a load, W, = unity (1 ton, 1 pound, 1 thousand kilograms, etc.). Each ordinate must then be multiplied by its corresponding load, measured in the corresponding unit, in order to obtain the required moment.

345. When W is at the point, *c*, we have $x = l - y$. Hence, ordinate, c' M, = maximum moment, $= W \cdot \frac{l - y}{l} \cdot y$; or, if W = 1, $c' M = \frac{l - y}{l} \cdot y$. The area of the diagram, *a'Mb'*, is $= \frac{l}{2} \cdot c' M = \frac{l}{2} \cdot \frac{l - y}{l} \cdot y = \frac{(l - y)\, y}{2}$.

---

* See "Calculation of the Stresses in Bridges for Actual Concentrated Loads," by Prof. Geo. F. Swain, "Trans. Am. Soc. C. E.," vol. XVII, July, 1887.

† Inasmuch as the load, in this discussion, occupies different positions at different times, it is not shown in Fig. 154.

346. If a load, = 1, be distributed over a length, = 1, at c, Fig. 155 (a), the resulting moment, at c, may be represented by the area of the rectangle standing on c', Fig. (b), the height of said rectangle being the ordinate, c' M, and its length = 1. Similarly, the moment, at c, due to a uniformly distributed load, $e\,f$, of 1 per unit length, Fig. (a), may be represented by the sum of the areas of the rectangles between e' and f', Fig. (b); and, if we suppose the load, $e\,f$, Fig. (a), of 1 per unit length, to be divided into a very large number of very narrow vertical strips, the resulting moment, at c, may be taken as represented by the area of the shaded trapezoid over $e'\,f'$, Fig. 155 (b). The moment, at c, due to a load of p (lbs., tons, etc.) per unit length, and occupying the same length, $e\,f$, is = p × area of trapezoid over $e'\,f'$, Fig. 155 (b).

347. Hence, the maximum moment, at c, due to a uniform load of p (lbs., tons, etc.) per unit of length, occurs when that load covers the entire span This maximum moment is = p × area a'Mb', $= p\,\dfrac{(l-y)\,y}{2}$. See ¶ 345.

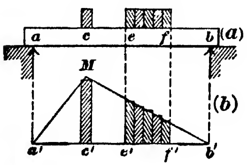

Fig. 155.

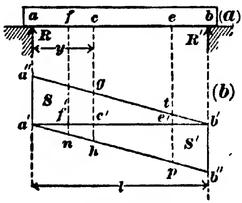

Fig. 156.

Influence Diagram for Shear.

348. Under a single concentrated load, the shear, at any point between the load and either support, is = the reaction of that support. See ¶¶ 326 and 327.

349. In the shear influence diagram, Fig. 156, as in the moment influence diagram, Fig. 154, let l be the span; x the variable distance of the load, W, from the right support, b, and y the constant distance, $a\,c$, of a given point, c, from the left support, a. Then, for any position of W, the left end reaction, R, or the shear, S, at any point between the load and the left support, is $= \mathrm{W} \,.\, \dfrac{x}{l}$; and the right reaction, R′, or the shear, S′, at any point between the load and the right support, is $= \mathrm{W} \,.\, \dfrac{l-x}{l}$.

350. The influence line for shear, like that for moments, ¶ 344, is usually constructed for a load = unity, so that $\mathrm{S} = \mathrm{R} = \dfrac{x}{l}$; and $\mathrm{S}' = \mathrm{R}' = \dfrac{l-x}{l}$. Each ordinate of the shear diagram must then be multiplied by W, in order to obtain the required shear.

351. Since W (= 1) and l are constant, R and S vary directly (and R′ and S′ inversely) with x. Thus, when W (= 1) is at b, we have $x = 0$; S = R = 0, and S′ = R′ = W = 1. When W (= 1) is at a, we have $x = l$, S = R = 1, and S′ = R′ = 0. Draw $a'\,a''$ and $b'\,b''$, each = W (= 1), and join $a''\,b'$ and $a'\,b''$. Then, with W at c, the (positive) shear, S, at each point, as f, between c and a, is given by the ordinate, $c'\,g$, to the line $a''\,b'$; while the ordinate, $c'\,h$, to the line, $a'\,b''$, gives the (negative) shear at each point, as e, between c and b.

352. Similarly, with W at e, the ordinate, $e'\,t$, gives the (positive) shear at each point, as c, between e and a; while $e'\,p$ gives the (negative) shear at each point between e and b.

353. It will be noticed that, as the load, W, passes from one side to the other of any point, as *c*, the shear at that point is reversed, the total change in shear being $= h\,c' + c'\,g = h\,g =$ the load, W.

354. With a load, W ($= 1$), at *b*, the shear at *c* is $= 0$. See ¶ 351. As the load advances from *b* toward *a*, the positive shear, $S = R = \frac{x}{l}$, at *c*, increases in proportion to the ordinates to the line $b'\,g$, becoming $= c'\,g = \frac{l - y}{l}$, when W is just to the right of *c*. With W just to the left of *c*, we have, negative shear at $c = S' = R' = c'\,h = \frac{y}{l}$. But as W proceeds from *c* to *a*, this negative shear, at *c*, decreases in proportion to the ordinates to the line $h\,a'$, becoming 0 when W reaches *a*. Thus, $a'hgb'$ is the shear influence diagram for the point, *c*. Similarly, $a'ptb'$ is the shear influence diagram for the point, *e*, etc.

355. If a series of nearly uniform and equidistant concentrated loads, such as the wheel loads of a locomotive and train, come upon the span, at the support, *b*, and advance toward *a*, the shear at *c* evidently increases until the first load reaches *c*. It is then suddenly diminished, by an amount = the first load, as that load passes *c*. It then continues to diminish, as each wheel passes over *c*, but more slowly, until the first load reaches *a*. See ¶ 358.

356. With a *uniformly distributed* load, of unity per unit length, moving as in ¶ 355, the shears at *c* (see ¶ 346) are represented by the *areas* of those portions of the diagram, $a'hgb'$, successively covered by the load, portions of the diagram below the zero line, $a'\,b'$, being taken as negative. Thus, when the head of the load reaches *e*, the (positive) shear at *c* is given by the area of the triangle, $b'\,e'\,t$. With head of load at *c*, the shear at *c* reaches its maximum, and is given by the area of triangle, $b'\,c'\,g$. With head of load at *f*, the shear at *c* is = area $b'\,c'\,g$ — area $f'\,c'\,h\,n$.

357. Similarly, the shears at *e* are given by the areas of portions of the diagram, $a'\,p\,t\,b'$.

358. Fig. 157* shows the influence diagram, 0 *d z* 14 16, for the shears at

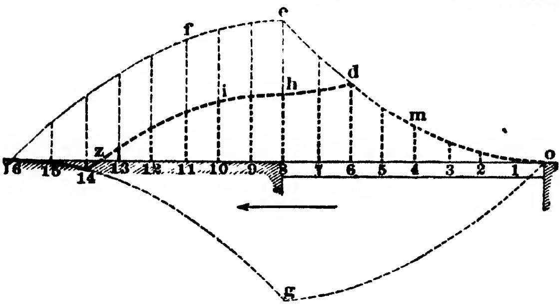

Fig. 157.

point 6, for a given uniformly distributed load, at least as long as the span, coming upon the span at point 0, passing across it, and leaving it at point 8; also the corresponding diagram, 0 *e* 16, for the left support, 8; and that, 0 *g* 16, for the right support, 0.

* First published in our 9th Edition, 1885.

Relation between Moment and Shear.

359. The shear, at any point in the span, is simply the **rate at which the bending moment is changing** at that point.

360. Thus, in Fig. 158, the moment, M, Fig. (*b*), at the support, *b*, due to the concentrated load, W, of 6 lbs., is = W l = 6 × 4 = 24 ft.-lbs.; but, between the support and the load, the moment is decreasing at the *uniform rate* of 6 ft.-lbs. for each foot of *x*, or 6 ft.-lbs. per foot = 6 lbs.; and this 6 lbs. is the *uniform shear*, V, Fig. (*c*), throughout the beam. Hence the shear diagram, Fig. (*c*), is a *horizontal* line; *i. e.*, its ordinates are of *equal* length.

361. Again, in Fig. 159, the shear diagram ordinates between *a*″ and *o*″, Fig. (*c*), are *positive*, showing the (algebraic) *increase* of the bending moment, M, Fig. (*b*), as we proceed from the left support, *a*, toward the center, *o*, of the span; while the *negative* shear diagram ordinates, between *o*″ and *b*″, show the (algebraic) *decrease* of the bending moment as we proceed from the center, *o*, to the right support, *b*. At the center, *o*, the rate of change of bending moment is zero, as is also the vertical shear.

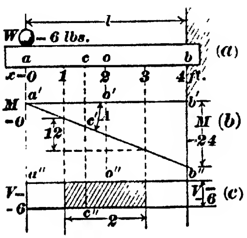

Fig. 158.

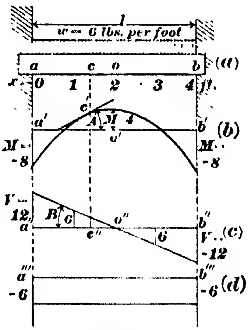

Fig. 159.

362. Both in Figs. 158 and 159, the bending moment, M, is constantly changing; but in Fig. 158 its *rate of change* (= 6 ft.-lbs. per ft. of span) is *constant*. Hence, the *moment* diagram is a *straight inclined* line, and the *shear* diagram is a *horizontal* line; whereas in Fig. 159 the rate of change of bending moment is constantly *varying*, being = 12 ft.-lbs. per foot of span (shear = 12 lbs.) at the support, and diminishing to zero at the center, *o*, of the span. Hence, in Fig. 159, the *moment* diagram, Fig. (*b*), is no longer straight, but *curved;* and the *shear* diagram, Fig. (*c*), is no longer horizontal, but *inclined*.

363. But, in Fig. 159 (*c*), the shear, V, or the *rate* of change of the bending moment (although no longer *constant*, as it was in Fig. 158 (*c*)), nevertheless *diminishes uniformly*, as we proceed from *a* toward *b*. Thus, at the point, 1, Fig. 159, midway between *a* and *o*, the bending moment is changing at the rate of 6 ft.-lbs. per foot, or *half* as fast as at *a*. Hence, the shear diagram, although no longer a *horizontal* line, is still a *straight* line; and the *uniform* decrease (= 6 ft.-lbs. per foot per foot) in the rate of change of the bending moment, or the *uniform* decrease (= 6 lbs. per foot) in shear, is indicated by the *horizontal* diagram in Fig. 159 (*d*).

364. In either Fig., let a straight line be drawn, tangential to the moment diagram (*b*), at any point, *c*′, and forming, with the horizontal zero line, *a*′ *b*′, an angle, A. (In Fig. 158, this line coincides with the moment diagram.) Then the tangent of A is given by the shear diagram ordinate, *c*″, corresponding to the point, *c;* or, for any point, V = tan A.

365. In Fig. 158, where this angle, A, Fig. (*b*), is *constant*, the shear ordinates, Fig. (*c*), are of *constant* length. In other words, the shear diagram, Fig. 158, is a *horizontal* line.

366. Since the shear diagram ordinates represent *forces* (as in lbs., etc.) and the abscissas represent *distances* (as in ft., etc.) the product of the distance between any two shear ordinates, multiplied by the mean of those ordinates, is an *area* representing a *moment* (in ft.-lbs., etc.). This moment is = the *difference* between the two moments represented by the corresponding ordinates in the moment diagram.

367. Thus, in Fig. 158 (*b*), the increase in (negative) bending moment, between points 1 and 3, is = 18 — 6 = 12 ft.-lbs.; and, in Fig. 158 (*c*), the moment represented by the (shaded) area, between the same two points, is = 2 ft. × 6 lbs. = 12 ft.-lbs. In Fig. 159, the (algebraic) increase in bending moment, Fig. (*b*), between the left support, *a*, and the center, *o*, of the span, is = 8 + 4 = 12 ft.-lbs.; and the moment, represented by the shear diagram area (triangle) between the same two points, Fig. (*c*), is

$$= \frac{1}{2} V \frac{l}{2} = \frac{12 \times 2}{2} = 12 \text{ ft.-lbs.}$$

368. Again, in Fig. 159, at any two points equally distant from the center, *o*, of the span, the moments are equal; or difference of moments = zero; and, since shear ordinates *below* the zero line, $a'' \, b''$, Fig. (*c*), are considered as *negative*, the algebraic sum of the two corresponding shear triangles, Fig (*c*), is also = zero.

Similarly, areas in Fig. 159 (*d*) correspond to differences of ordinates in Fig. 159 (*c*).

Diagram for Reactions, Shears and Moments.

369. In Fig. 58 (*b*), p. 385, *c w* and *w X* give respectively the **reactions** of the right and left supports, *w* and *x*, Fig. 58 (a).

The shear, pp. 446, &c., is constant for all the sections between any two loads. For the shear in any such section, as *d*, find, in the equilibrium polygon, Fig. 58 (*b*) the lines, *c w* and *b c*, representing the forces, *w* and *c*, to the right, or those, *w X*, *X a* and *a b*, representing the forces *x*, *a* and *b*, to the left, of the section. Then the line, *b w*, = *c w* — *b c*, or *w b* = *w X* *X a* *a b*, represents the resultant of either set of forces, and thus represents the shear in the section, *d*.

To find the bending moment in any section, as *d*, Fig. 58 (*a*); from *d* draw a vertical, cutting the lines *s r* and *n p* of the cord polygon, and let *y* = the length of the ordinate, intercepted on the vertical, between these lines.

Produce *s r* and *n p* to intersect, as at *e*. Then *e* is the point of application of the resultant, *U* = *b w*, Fig. 58 (*b*), of the two forces to the right of *d*, viz: of the load *c*, represented, in Fig. 58 (*b*) by *b c*, and the reaction at *w*, represented by *c w*; for, if the load, *c*, and the reaction at *w* were removed, we should require, for equilibrium, a vertical reaction, *b w* = *c w* *b c*; and the corresponding lines, *b O* and *w O*, in the force diagram, are respectively parallel to *n p* and *s r* in the cord polygon.

In other words, by eliminating the load, *c*, and the reaction at *w*, and substituting their resultant, *U* = *b w*, we substitute also a new cord polygon, *s m n e s*, Fig. 58 (*a*), with *U* (= *b w*) applied at *e*.

In section *d*, let *L* be the lever arm of this resultant, *U*, = the horizontal distance from *e* to *y*. In Fig. 58 (*b*), draw *O h* horizontal, representing the horizontal component of each of the stresses, *X O*, *a O*, etc. Let *H* = the length of *O h*. Then the bending moment, in section *d*, is *M* = *H y*; for *M* = *U L*; and, by similar triangles, *L* : *y* = *H* : *U*; or *U L* = *H y*.

Scale of moments. Since *M* = *H y*, we can, by choosing the position of *O** at the proper distance from *X c*, obtain any desired scale of moments by which to measure moments directly, upon *y*. Thus, suppose that a scale of 1 inch = 2 feet has been used in Fig. 58 (*a*), and that it is desired to have a moment scale of 1 inch = 50 ft-lbs. Then we need only so choose the position of *O** that its distance, *H*, from *X c*, shall represent 50 ft-lbs 2 ft = 25 lbs, by the scale of Fig. 58 (*b*). Then 1 inch, in length of *y*, will correspond to 2 ft × 25 lbs. = 50 ft-lbs.

---

* See p. 378, ¶ 95.

STRENGTH OF MATERIALS.

GENERAL PRINCIPLES.

Stress.

1. Stress occurs when forces act upon a body in such a way that its particles tend to move simultaneously with different velocities or in different directions; to do which, the particles must change their relative positions. This occurs, for instance, when a body is so placed as to oppose the relative motion of two other bodies, as when a block is placed between a weight and a hor table. Here the two bodies (the wt and the table) tend to come closer together; but they cannot do so without distortion of the intervening block; and such distortion is resisted by **internal forces,** acting betw the particles of the block and tending to keep those particles in their original relative positions. The action of these internal forces is called **stress.***

2. Similarly, if a body be suspended by a long chord, and if we push or pull the body to one side, the particles, on the side acted upon, will first tend to move, and the transmission of this tendency to the remaining particles causes stress within the body.

3. For internal equilibrium, **the internal stresses must balance the external forces.** Hence, it is not unusual to apply the term, "stress," indifferently to either.

4. Let the two forces, a and b, Figs A, B, acting upon the body, o, meet at an angle, $a\ o\ b$. Then the two equal and opposite **components,** $a''\ o$ and $b''\ o$, cause compressive or tensile stress in the body, o, as in ¶ 1; while the other two components, $a'\ o$ and $b'\ o$, unite to form the resultant, $c\ o$, which, unless balanced by other forces, moves the body, o, in its own direction, causing, as in ¶ 2, another comp stress, Fig A, or tensile stress, Fig B

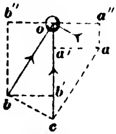

Fig. A.

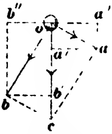

Fig. B.

5. Upon any plane within a body, a force may act **(1) normally, (2) tangentially, or (3) obliquely.** If it act obliquely, it may be resolved into two components (see Statics, ¶ 65, p 372), one acting normally and the other tangentially, upon the plane.

6. Consider the two portions into which the body is divided by such a plane Then **(1)** forces, acting **normally** upon the plane, produce **tension** (or **compression**) in the plane, tending to separate the two portions (or to push them closer together); and **(2)** forces, acting **tangentially** upon the plane, produce **shear** (or **torsion**) in the plane, tending to slide the two portions one past the other in a straight line (or with a twisting motion). **Torsion occurs** in planes betw and parallel to **two contrary couples,** as in cross sections of a hand-brake axle when the brake is applied.

7. Thus, if an iron bar be pulled (or pushed) lengthwise, its cross sections sustain normal tension (or compression). If it be sheared across (or twisted), the cross sections, between and parallel to the two shearing (or twisting) forces, sustain shearing (or torsional) stress.

8. At any point, in the circular path of a torsional stress, we may consider the tangents to the path as representing shearing forces. **Torsion** is

* In every-day language, and often in the writings of engineers, this action of the internal forces, or the external force causing it, is called "strain", but scientists apply the word "**strain**" to the *deformation* occurring under stress. See "**stretch,**" ¶¶ 11 etc.

therefore merely a **shearing** stress in which the direction changes at each point.

9. Transverse stress. In Fig 124, p 438, the two equal and parallel forces, W and R, in opposite directions, cause a tangential or *shearing* stress, $= W = R$, in the vertical planes lying between their lines of action; but W and R, as a *couple*, have a *moment*, which, for equilibrium, must be resisted by the equal and opposite moment of another couple, as C and T; and the opposition of these two couples causes normal (comp and tensile) stresses in the same vert planes parallel to and betw W and R.

10. The ultimate tendency of any opposing external forces is to fracture the body by *increasing* the distances between its particles. Even under *compressive* stress, rupture can occur only by *separation* of particles.

Stretch.

11. When the internal stresses and the external forces are in equilibrium, no distortion takes place, but, at the instant when opposing external forces are first applied to a body, the internal stresses are not yet developed, and **distortion** begins, under the unopposed action of the external forces. See ¶¶ 35 etc. But the stresses are brought into action by the distortion, and they increase with it, and, if the external force is not increased beyond the elastic limit (¶ 26) the stresses finally equal the external forces, and prevent further distortion.

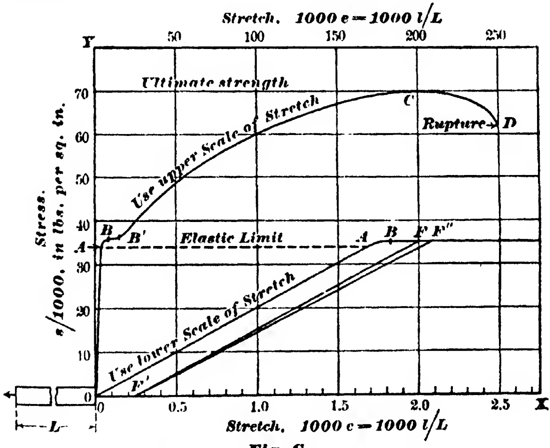

Fig. C.

Behavior under Normal Stresses.

12. Fig C represents the **behavior of a typical material** (mild steel) **under tension.** From 0 to A, i.e., under stresses up to the **elastic limit** (¶ 26), say 34,000 lbs per sq inch, the stretch progresses proportionally with the stress, as indicated by the straight line, 0 A. (The earlier portions of the process are represented, in the *lower* diagram, to a scale of stretch 100 times as great as that of the upper diagram.) After passing the point A, the stretch increases faster than the stress; and, betw B and B', the stretch (in iron and steel) increases with little or no increase of stress, or even under a slightly diminishing stress.* B is called the **yield point.** See ¶ 31. The scale of the lower diagram does not extend to B'. Beyond B' (upper diagram), the stretch increases much less rapidly than betw B

* See ¶¶ 16, 17

and B', and remains, for a time, nearly proportional to the stress* (though much greater, relatively to stretch, than in $0\ A$); but the stretch now proceeds faster and faster, and in increasing ratio with the stress, until the stress reaches its maximum or **ultimate** value (say 70,000 lbs per sq inch) at C. At C, the stretch is increasing without increase of stress (diagram horizontal), and, beyond C, the stretch continues increasing altho the stress is diminishing, until, finally, at D, **rupture** occurs.

13. If, after passing the elastic limit, the bar is relieved from stress, as at F, Fig C, lower diagram, its recovery is incomplete, the length remaining somewhat greater than in its original unstressed condition. The permanent increase, $0\ F'$, is called the **permanent set.** or simply the **set.** The line $F\ F'$ is, in general, approx parallel to the line, $0\ A$, of elastic stretch. When the same stress is again applied, the stretch is greater than before, by a small amount represented by $F'\ F''$.

14. When the stress is **within the elastic limit** (¶ 26), **the recovery**, upon release from stress, is so nearly complete that the permanent set cannot be indicated in our Figs. (¶ 28.)

15. Under *tension*, the **sec area** is *diminished*, and, under *compression increased*. In ductile materials, under tension, the reduction of sec area is very marked, especially along a relatively short portion of the length, usually near the middle of said length; and fracture occurs normally at the point of maximum reduction.

16. In Fig C, both diagrams, and, in Fig D, the *solid* curves, represent the **nominal unit stresses**, or those usually stated. These are found by dividing the total stresses, respectively, by the *original* section area, as in ¶ 18.

17. The *dotted* curves, Fig D, represent the **actual unit stresses**, found by dividing the total stresses, respectively, by the *actual* section area, as diminished or increased by stress. Under *tension*, the actual unit stresses are of course *greater*, and, under *comp*, *less* than the corresponding nominal unit stresses.

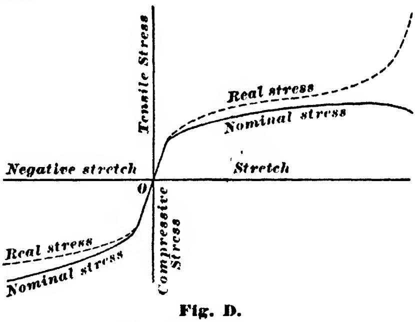

Fig. D.

Elastic Modulus. Fig. C.

18. Let P = the **load** (one of the two equal and opposite external forces) acting at one end of a bar and in line with the axis of the bar; and let a = the original* cross-section area, or **section area**, of the bar, normal to its axis. Then, s, = $P\ /\ a$, is the normal stress *per unit of area*, or stress *intensity*, or normal **unit stress**, in the bar. We assume that, so long as the external force acts axially, P is *uniformly* distributed over a, altho this is seldom strictly the case in practice.

* See ¶¶ 16, 17

19. Let L = the original length of the bar, or of some designated portion of that length, and l = the **stretch** * which takes place, in the length, l, under the action of a given unit stress, s. Then, e, = l / L, is the stretch *per unit of length*, or **unit stretch.*** corresponding to the unit stress, s.

20. In many materials, the unit stress, s, and the unit stretch, e, at first increase *proportionally*, the ratio, s/e, or unit stress ÷ unit stretch, remaining practically constant. This ratio is called the **elastic modulus**, and is designated by E, or

Elastic modulus = E = s/e = unit stress ÷ unit stretch.

20 a. The elastic modulus is thus **proportional to the tangent** of the angle, X 0 1, Fig C, the proportion depending upon the scales adopted.

20 b. The elastic modulus, E, increases with the unit stress reqd to produce a given unit stretch. Hence E is a measure of the *stiffness* of a body, i.e., of its ability to resist change of shape. "**Stiffness modulus**" would have been a better name.

20 c. If equal additions of stress could indefinitely continue producing equal additional stretches in a bar, beyond as well as within the elastic limit (¶ 26), then a stress, equal to the elastic modulus, would *double the length* of a bar when applied to it in *tension*, or would *shorten it to zero* in *compression*.

20 d. For example, within the elastic limit, a one-inch square bar of rolled steel will stretch or shorten, on an average, about $\frac{1}{30,000}$ of its length under each additional load of 1000 lbs. If it could stretch or shorten indefinitely at the rate of $\frac{1}{30,000}$ of its *original* length for each 1000 lbs. of added load, then 30,000 times 1000 lbs., or 30,000,000 lbs., (which is about the average modulus of elasticity for such bars) could either stretch the bar to double its length or reduce it to zero.

20 e. If equal infinitesimal stresses, applied to a bar, could indefinitely produce stretches, each bearing a *constant ratio to the increased length of the bar*, if in *tension*; or to the *diminished* length, if in *compression*; then the same load which would *double* the *original* length of the bar, if applied in *tension*, would reduce it to *half* its *original* length, if applied in *compression*.

---

* We regard *shortening*, under *compression*, as *negative* stretch.

21. In a prismatic bar, under longitudinal tension or compression, let

W = the total load;
a = the cross section area;
$s = \frac{W}{a}$ = the unit stress = the stress per unit of area;
L = the original length;
l = the stretch*;
$e = l/L$ = the unit stretch* = the stretch* per unit of original length;
E = the elastic modulus of the material;
$r = E\,a$ = a measure of the resistance of the bar

Then

Elastic modulus $= E = \frac{W}{a} \cdot \frac{L}{l} = s/e$ .... (1)

Total load $= W = E\,a\,\frac{l}{L} = r\,e$ .... (2)

Unit stress $= s = \frac{W}{a} = E\,e$ .... (3)

Total stretch* $= l = \frac{W}{a} \cdot \frac{L}{E}$ .... (4)

$= s \cdot \frac{L}{E}$ .... (5)

Unit stretch* $= e = \frac{l}{L} = \frac{W}{a\,E} = \frac{s}{E}$ .... (6)

22. In a beam, supported at both ends and loaded at the center, let

L = length of clear span of beam;
w = weight " " " " ;
$\triangle$ = deflection " " " " ;
b = breadth of cross section of beam;
d = depth " " " " ;
I = moment of inertia " " " "

Then

$$E = \frac{(W + 5/8\,w)\,L^3}{48\,\triangle\,I} \quad \text{............} \quad (7)$$

If the beam is rectangular, $I = \frac{b\,d^3}{12}$ (p 469), and

$$E = \frac{12\,(W + 5/8\,w)\,L^3}{48\,\triangle\,b\,d^3} = \frac{(W + 5/8\,w)\,L^3}{4\,\triangle\,b\,d^3} \quad \text{............} \quad (8)$$

For beams, see also pp 480–481.

23. Reciprocal of elastic modulus. The elastic modulus, $\frac{\text{unit stress}}{\text{unit stretch}}$, indicates the *stress* required to produce a certain *distortion*

Its reciprocal, $= \frac{\text{unit stretch}}{\text{unit stress}}$, shows to what extent a bar etc of a given material must be *distorted* in order to produce a given *stress*. This may be of great importance, especially in the design of structures of timber, the elastic modulus of which is low, relatively to that of steel, and in which, therefore, a relatively great distortion must take place before a given fiber stress (such as the maximum safe fiber stress) can be brought into action Thus, in the case of a wharf, supported by long timber piles, the piles may submit to so great a lateral deflection as to give the load, resting upon them, a dangerously great horizontal leverage, and thus a dangerous overturning moment.

* *Compression* is regarded as *negative* stretch.

24. Variable elastic modulus. Fig 11, Concrete experiments 81*a* p 1340, shows an example (in both tension and compression) of a material in which the elastic modulus, *E*, is constantly changing; the stretches, from the first, increasing faster than the stresses.

25. Even in the case of ductile materials, the stretches, produced by stresses within the elastic limit (¶ 26), are so small and so irregular that a satisfactory average value of the elastic modulus can be arrived at only by comparing the results of many experiments. In the case of brittle materials, where scarcely any perceptible stretch takes place before rupture, the determination of the elastic modulus is very uncertain.

Elastic Limit.

26. The stress, 0 *A*, Fig C, beyond which the stretches in any body increase perceptibly faster than the stresses, is called its **elastic limit**, or limit of elasticity. Owing to the irregularity in the behavior of different specimens of the same material, and to the extreme smallness of the distortions caused in most materials by moderate loads, and because we often cannot decide just when the stretch begins to increase faster than the load, the elastic limit is seldom, if ever, determinable with exactness and certainty.* But by means of a large number of experiments upon a given material we may obtain useful average or minimum values for it, and should in all cases of practice keep the stresses well within such values, since, if the elastic limit be exceeded (through miscalculation, or through subsequent increase in the stress or decrease in the strength of the material) the structure rapidly fails. The table, p 460, gives approximate average elastic limits for a few materials. The elastic limit, as here defined, is sometimes called **the "true" elastic limit.** Compare ¶ 31.

27. Brittle materials, such as stones, cements, bricks, etc., can scarcely be said to have an elastic limit; or, if they have, it is almost impossible to determine it; since rupture, in such bodies, takes place before any stretch can be satisfactorily measured.

28. A small **permanent "set"** (stretch) probably takes place in all cases of stress even under very moderate loads; but ordinarily it first becomes noticeable at about the time when the elastic limit is exceeded. **The elastic limit is sometimes defined** as that stress at which the first marked permanent set appears.

29. The elastic ratio of a material is the quotient, $\frac{\text{elastic limit}}{\text{ultimate strength}}$. It is usually expressed as a decimal fraction.

The permissible working load of a material should be determined by its elastic limit rather than by its ultimate strength. Hence, other things being equal, a high elastic ratio is in general a desirable qualification; but, on the other hand, it is possible, by modifying the process of manufacture, to obtain material of high elastic ratio, but deficient in "body" or in resilience—*i. e.*, in capacity to resist the effect of blows or shocks, or of sudden application or fluctuation of stress. See ¶ 34; also ¶¶ 35 etc.

In the manufacture of steel, the elastic ratio is increased by increasing the reduction of area in hammering or rolling, and the rate of increase of elastic ratio with reduction of area increases rapidly as the reduction becomes very great. Kirkaldy found†

for steel plates	1 inch thick, mean elastic ratio	=	0.53
" " "	¾ " " " " "	=	0.53
" " "	½ " " " " "	=	0.54
" " "	¼ " " " " "	=	0.61

---

* The U. S. Board appointed to test Iron, Steel, &c., found a variation of nearly 4000 lbs. per square inch in the elastic limit of bars of one make of rolled iron, prepared with great care and having very uniform tensile strength; and, in another very carefully made iron, a difference of over 30 per cent. between two bars of the same size. Report, 1881, Vol. 1, p. 31.

31. Yield point. Commercial, Relative or Apparent Elastic Limit. In testing specimens of iron and steel, it is commonly found that, at a stress slightly exceeding the true elastic limit (¶ 26), the stretch begins to increase without further increase of load. This point is usually called "the yield point," or "the elastic limit" in commercial testing. The French Commission on Methods of Testing the Materials of Construction called it the "apparent elastic limit." The late Prof. J. B. Johnson ("The Materials of Construction," New York, John Wiley & Sons, 1906, p. 19) applied the term, "relative or apparent elastic limit" to that point on the stress diagram at which the rate of deformation is 50 per cent. greater than at points below the true elastic limit.

Resilience.

32. The resilience of a bar, under a stress, s, is the work done, upon the bar, in producing that stress, or, theoretically, the work which the bar will do, in regaining its original shape, when relieved from stress. Usually we are concerned with the **elastic resilience,** or that corresponding to the stress, s_e *at the elastic limit.*

33. Let

s_e = the unit stress at the elastic limit;

a = the section area of the bar,

$P_e = a\ s_e$ = the load corresponding to s_e;

L = the original length of the bar;

l = its stretch, at the elastic limit;

E = the elastic modulus.

*In rolled iron and steel, the elastic modulus is remarkably constant for all grades. In wrought iron, the elastic limit depends chiefly upon the degree of reduction of cross section in rolling; the smaller sizes having the higher elastic limit. In steel, this effect is less marked.

† See ¶¶ 25, 26.

‡ In wood, "the extreme fiber stress at the true elastic limit (¶ 26) of a beam is practically identical with the compressive stress endwise of the material," table, p. 1138. See discussion by S. T. Neely, in "Timber Physics," 1889 to 1898, by Filibert Roth, House Document No. 181, 55th Congress, 3d Session, Washington. 1899, p. 374.

The work has been done by the *mean* load, $P_e/2 = a\,s_e/2$, acting thru the dist, $l = L\,s_e/E$. Hence,

Resilience $= K = P_e\,l/2 = a\,s_e\,L\,s_e\,/2\,E = (s_e^2/2\,E)\,a\,L$.

34. Here $s_e^2/2\,E$ is the

resilience modulus = resilience of a bar of unit section area and unit lgth.

The resilience modulus of a material is a measure of its capacity for resisting shocks or blows.

Suddenly applied loads.

35. Let a body, of weight, W, be suspended by a string, and let it just touch the scale-pan of a spring balance, without depressing it. Now let the string be cut with a pair of scissors.

36. At the moment of cutting, the spring has not been stretched; its resisting stress, S, is therefore zero, and the net or resultant downward force, acting upon the body, is $F = W - S = W - 0 = W$.

37. Under the action of this force, the spring stretches, and S increases proportionally with the stretch. Hence (W remaining constant) the resultant downward or accelerating force, F, acting upon the body, decreases until $S = W$, when $F = W - S = W - W = 0$.

38. The body, having thus far been constantly accelerated, (by a diminishing force, F), has constantly increased its velocity. Let h = the height thru which it has now fallen, and let x be the point reached, at the end of h.

39. Beyond x (W remaining constant, while S continues to increase), the moving body is acted upon by a constantly increasing, retarding upward force, $-F = W - S$, which brings it to rest at a second point, z, at the end of a second distance = h. Its **total fall** is therefore $2\,h$.

40. Let S max = the max value of S, or that at the end, z, of the fall, $2\,h$. Then, since S has increased proportionally with h, its *mean* value, during the fall, $2\,h$, was S max$/2$; and the work done, during the entire fall, $2\,h$, was $2\,W\,h$ = (S max/2) $2\,h$ = S max $\times\,h$. Hence,

S max = 2 W.

41. At the end, z, of the fall, $2\,h$, the body, having come to rest, is acted upon by an upward force, $-F = W - S$ max $= W - 2W = -W$; and (neglecting friction) the same performance is now repeated, but in the upward direction, and so on indefinitely.

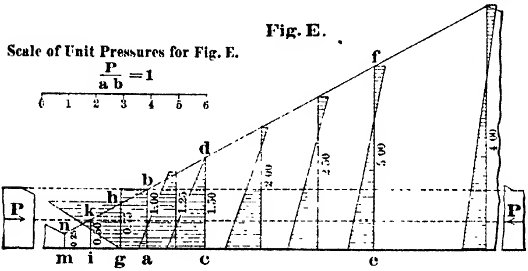
42. But losses of energy, due to air resistance and to internal friction, render each oscillation less than its theoretical value; and the body therefore finally comes to rest at the point, x, midway of the fall, $2\,h$.

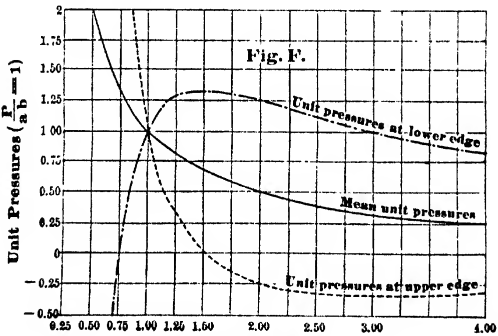
43. Thus (¶ 40), within the elastic limit, **a load, suddenly applied** (tho without shock) **produces temporarily a stretch** nearly equal to **twice that which it could produce if applied gradually:** *i.e.*, twice that which it can maintain after it comes to rest; and develops temporarily, in the stretched body, **a resisting stress = twice the load.**

44. If the load be added in small instalments, each applied suddenly, then each instalment produces a small temporary stretch, and afterward maintains a stretch half as great. Under the last small instalment of load, the spring stretches temporarily to a length greater than that which the total load can maintain, by an amount equal to half the small temporary stretch produced by the sudden application of the last small instalment.

A section may be weakened by increasing its width. On pp 400, etc., we considered the case where the width of the base is fixed and where the point of application of the resultant of the forces acting upon it is shifted to different positions along the base We will now notice the case where the resultant is applied at a constant distance from one end of the base, but where the base is of varying width, so that this constant distance may be equal to, or greater or less than, the half width of the base.

Let Fig. E represent a side view of a bar of uniform thickness = 1,* but (as





shown) of varying width, and subjected to pressures, the resultant P of which is = 1,* and passes through the center of that section $a\,b$ whose width is 1 * †

* We adopt the value 1 for the pressure P, the width $a\,b$, and the thickness merely in order to facilitate the explanation. It is not essential to the application of the principle.

† We here suppose ourselves dealing with a perfectly rigid and homogeneous material. In practice, these values would be more or less modified by yielding of the particles under stress, by unevennesses in the surfaces of the supposed cross sections, etc. Nevertheless, the general principles here laid down hold good.

The pressure per unit of area of cross section (or "unit stress") in the section ab is then $\frac{P}{ab \times 1} = \frac{P}{1} = P = 1$*, and may be assumed to be uniformly distributed over it.

But at other sections of the bar the resultant is nearer to one edge than to the other, and the unit stress can then no longer be assumed to be uniformly distributed over the cross section, but, as explained on pp 400 to 403 is a maximum at the edge nearest to the resultant, and diminishes gradually and uniformly to a minimum at the farther edge.

This is indicated by the shaded triangles, etc., in Fig. E and by the curves in Fig. F, which show, for the several sections in Fig. E, the mean unit stress* and the unit stresses at the upper and lower edges respectively, calculated by the rules on pp 401–404.

These stresses are also given in the following table:

Unit Stresses in Fig. E; the unit stress $\frac{P}{ab}$ in section ab being taken as 1.†

Section.	Width.	Stress per unit of area of cross section.		
		Mean.	At lower edge *m e*.	At upper edge *n f*.
	4.00	0.25	0.8125	− 0.3125 ‡
e f	3.00	⅓	1.00	− ⅓
	2.50	0.40	1.12	− 0.32
	2.00	0.50	1.25	− 0.25
c d	1.50	⅔	1⅓	0
	1.25	0.80	1.28	0.32
a b	1.00	1.00	1.00	1.00
g h	0.75	1⅓	0	2⅔
i k ¶	0.50	2.00	− 4 ‡	8.00
m n ¶	0.25	4.00	− 32 ‡	40.00

It is important to notice that for a given force P, and for widths less than 3 ab, the strongest section of this bar is *not the widest one*, but that (ab) at which the resultant P passes through the center of the section. In other words, **a bar may be weakened by additions to its cross section** if those additions are such as to cause the resultant of the pressures to pass elsewhere than through the center of any cross section. This fact is entirely independent of the *weight* of the added portion.

Among the sections wider than ab, the weakest is that (cd) whose width is = 1.5 ab. At that section the lower edge me has its maximum unit stress $\left(= 1\frac{1}{3} \times \frac{P}{ab}\right)$ while at d in the upper edge there is no pressure. Beyond cd the upper edge nf is in *tension* ‡ and the unit pressure along me decreases, becoming again $= \frac{P}{ab}$ at ef, where the width ef is $= 3\,ab$, and decreasing still further with further increase in width.

---

* In the case discussed on pp 400 to 403, the mean pressure $un = \frac{P}{uv}$, remained constant so long as the entire surface uv was called into play. Here, on the contrary, the area of the section varies. Hence the mean unit pressure varies also, and inversely as the area

† See foot-note *, p. 462.

‡ In the present discussion, as well as in that on pp. 400 to 403, we have assumed cases of *compression* for illustration, but the principle involved applies equally to cases where the force applied is *tensile*. In such cases, however, the terms "pressure" and "tension" are of course reversed

¶ The unit stresses at the edges in section ik are too great to be shown conveniently in either figure; while those in section mn (as the table shows) far exceed the limits of the figures. The pressure at k would be $\frac{P}{0} = \infty$ (infinity) were it not for the tensions in the lower part of the section.

When the width becomes *less* than that at $a\,b$, as at $g\,h$, etc., the *upper* edge of the bar comes nearer to the resultant than the lower edge, and hence receives the maximum pressure.

When the width $= \frac{3}{4}\,a\,b$, as at $g\,h$, the distance of the resultant from the upper edge is $\frac{1}{3}$ the width of the section. The pressure at the lower edge is then $= 0$; the mean pressure in $g\,h$ is $\frac{P}{a\,b} \times \frac{1}{0.75} = 1\frac{1}{3} \times \frac{P}{a\,b}$, and the pressure at the upper edge is twice the mean pressure in $g\,h$, or $2\frac{2}{3} \times \frac{P}{a\,b}$.

When the width becomes less than $\frac{3}{4}\,a\,b$, as at $i\,k$ and $m\,n$, the pressure at the lower edge $m\,e$ becomes negative or tensile.* Thus, when, as at $i\,k$, the width is $= \frac{1}{2}\,a\,b$, and the resultant passes through the upper edge, the unit pressure at that edge is $= 8 \times \frac{P}{a\,b}$, while the lower edge sustains a *tension* of $4 \times \frac{P}{a\,b}$; and, as the section is further reduced, these stresses are still further and very rapidly increased.

The condition of those sections (such as $m\,n$) where the line of the resultant passes outside the section, is similar to that of the section $m\,n$ of a bent hook sustaining a load, as in Fig. G.

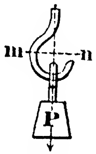


Fig. G.

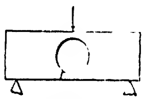

Fig. H.

Messrs. William Sellers & Co., of Philadelphia, had occasion to test a number of cast-iron beams, each having a large circular opening, as in the annexed figure. These beams broke, not at the smallest section directly under the center of the opening, but a little to one side, where the section was deeper, as indicated in Fig. H.

Fatigue of Materials. In the following articles on Strength of Materials, the ultimate or breaking load is that which will, during its first application, rupture the given piece within a *short* time. But Wohler's and Spangenberg's experiments show that a piece may be ruptured by **repeated applications** of a load much *less* than this; and that the oftener the load is applied the less it needs to be in order to produce rupture. Thus, wrought iron which required a tension of 53000 lbs per sq inch to break it in 800 applications, broke with 35000 lbs per sq inch applied about 10 million times; the stress, after each application, returning to zero in both cases.

The *diff* between the maximum and minimum tension in a piece subjected to tension only, or between the max and min compression in a piece subjected to comp only; or the *sum* of the max tension and max comp in a piece subjected alternately to tension and comp; is called the **range of stress** in the piece. Stresses alternating between 0 and any point within the elastic limit may be repeated many million times without producing rupture.*

For a given number of applications, the load required for rupture is least when the range of stress is greatest. If the stress is alternately comp and tension, rupture takes place more readily than if it is always comp or always tension. That is, it takes place with a less range of stress applied a given number of times, or with a less number of applications of a given range of stress. For a given range of stress and given number of applications, the most unfavorable condition is where the tension and comp are equal.

The fatigue of materials is taken into consideration in designing members of important structures subject to moving loads. See Truss specifications, pp 760, 761.

Experiments show that materials may fail under a **long continued stress** of much less intensity than that produced by the ult or bkg load.

---

* This does not always hold in cases where the elastic limit has been artificially raised by process of manufacture, etc. Oft-repeated alternations between tension and compression below such a limit reduce it to the natural one. A slight flaw may cause rupture under comparatively few applications of a range of stress but little greater, or even less, than the elastic limit. Rest between stresses increases the resisting power of a piece. In many cases, stresses a little beyond the elastic limit, even if oft-repeated, raise that limit and the strength but render the piece brittle and thus more liable to rupture from shocks; and a little further increase of stress rapidly lessens, or may entirely destroy, the elasticity. A *tensile* stress above the elastic limit greatly lowers, or may even destroy, the *compressive* elasticity, and vice versa. If a tensile stress, by stretching a piece, reduces its resisting area, it may thus reduce its *total* strength, even though the strength *per sq in* has increased. Mr B Baker finds that hard steel fatigues much faster under repeated loads than soft steel or iron.

TRANSVERSE STRENGTH.

1. In Statics, ¶¶ 285, etc., we discuss the action of external or destructive forces upon cantilevers, beams and trusses. We here discuss the reaction of the internal or resisting forces (stresses) in solid cantilevers and beams, in order to determine their loads. See also ¶¶ 104, etc.

2. Unless otherwise stated or apparent, we assume that the stresses in all parts of the cantilever or beam are within the elastic limit.

Conditions of Equilibrium.

3. For equilibrium, the internal forces, and their moments, must balance the external forces and their moments. In other words, if the cantilever or beam be supposed cut by a section at any point, we must have

(1) Σ vertical forces = 0
(2) Σ horizontal forces = 0
(3) Σ moments = 0

Or:

(1) Algebraic sum of the internal vertical *stresses* = algebraic sum of the external vertical *forces* on either side of the section;

(2) Sum of horizontal *tensile* stresses = sum of horizontal *compressive* stresses; and

(3) Algebraic sum of the moments of the internal *stresses* = algebraic sum of moments of external *forces* on either side of the section.

4. Cantilevers and beams of uniform cross-section have usually a superabundance of strength against shearing, and fail (if at all) where the bending moment is greatest. Hence the discussion of their resistance turns principally upon equilibrium of *moments*. For their resistance to vertical shear, see Statics, ¶¶ 325, etc., and p. 499. See also Horizontal Shear, ¶¶ 51 to 53, below.

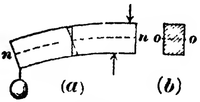

Fig. 1.

5. For equilibrium, therefore, the resisting moment, R (= the sum of the resisting moments, r, of all the particles in any cross-section of the cantilever or beam, Fig. 1 or 2), must be equal to the bending moment, M, or algebraic sum of the moments of all the external forces on either side of the section.

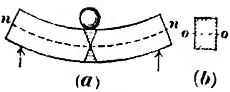

Fig. 2.

Reactions of Fibers.

6. In a *truss* or *framed* beam (see Trusses) the resistance of each of its two chords is regarded as acting in a line passing through the centers of gravity of the cross-sections of the chord; but, in a solid cantilever, Fig. 1, or beam, Fig. 2, the total resisting moment is the sum of the separate resisting moments of the several fibers throughout the cross-section.

Neutral Surface. Neutral Axis.

7. When a cantilever (or beam) bends, the fibers in the upper (or lower) part of each cross-section are extended, while those in the lower (or upper)

part are compressed (see Figs. 1 and 2); the extension and compression being greatest at the top and bottom of the section, and thence decreasing uniformly inward toward a surface, *n n*, Figs. (*a*), near the center of the cross-section. In this surface, which is called the **neutral surface**, the fibers are neither extended nor compressed. The line, *o o*, Figs. (*b*), formed by the intersection of the neutral surface with any cross-section of the cantilever or beam, is called the **neutral axis** of that section.

8. In order that the algebraic sum of all the horizontal stresses in the cross-section may be zero, as required for equilibrium, the neutral axis must pass through the center of gravity of the section. Hence, the neutral surface passes through the centers of gravity of all the cross-sections.

9. The neutral axis may be found by balancing the section (cut out of cardboard) over a knife-edge. Or see Center of Gravity, under Statics, ¶¶ 125, etc. Every section has an indefinite number of neutral axes, all passing through its center of gravity in as many different directions. The axis required, in any given case, is that one which is normal to the plane of the bending moment under consideration.

In the following discussion, we assume that the neutral axis of the section is normal to the line of action (usually vertical) of the load, as it generally is. For other cases, as, for instance, the case of roof purlins, see "The Determination of Unit Stresses in the General Case of Flexure," by Prof. L. J. Johnson, Boston Soc. of Civil Engineers, in Jour. Ass'n of Eng'ng Socs., vol. XXVIII, No. 5, May, 1902.

Resisting Moment. Unit Stress.

10. It is assumed that the extension or compression of each fiber, and therefore the resisting force actually exerted by it, is proportional to its vertical distance, *t*, above or below the neutral axis.

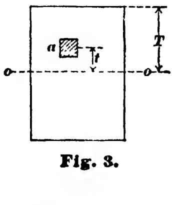

Fig. 3.

In Fig. 3, let

T = the distance from the neutral axis, *o o*, to the fiber farthest from that axis, either above or below the axis;
S = the unit stress in said farthest fiber;
t = the distance from the neutral axis to any given fiber;
s = the unit stress in said given fiber;
a = the area of said given fiber;
F = the total stress in said given fiber;
r = the resisting moment of said given fiber about the neutral axis;
M = bending moment at the cross-section under consideration;
R = the resisting moment of the entire cross-section;
= Σr = the sum of the resisting moments of all the fibers;
I = the moment of inertia of the cross-section. See ¶¶ 14, etc.;
= $\Sigma t^2 a$ = the sum, for all the fibers, of $t^2 a$;
X = the section modulus, $= \frac{I}{T} = \frac{R}{S}$. See ¶¶ 25, etc.

Then the unit stress, in any given fiber, is $= s = S \frac{t}{T}$; its total stress, F, is $= a s = S a \frac{t}{T}$; and its resisting moment, *r*, is $= F t = S a \frac{t^2}{T}$. Hence, the resisting moment, R, of the entire section, is

$$R = M = \Sigma r = \Sigma S a \frac{t^2}{T} = \frac{S}{T} \Sigma t^2 a = \frac{S}{T} \cdot I.$$

Hence also, $S = MT/I$; $I = MT/S = TX$; $T = SI/M$.
Since $S/s = T/t$, we have $S/T = s/t$, and

$$R = M = SI/T = sI/t = SX.$$

In beams of rectangular section (p 469), of breadth, B, and depth, D, we have $I = BD^3/12$, and $T = D/2$. Hence,

$$S = 12\,MT/BD^3 = 6\,M/BD^2; \text{ and}$$
$$R = M = SBD^3/12\,T = SBD^2/6$$

When beams are tested to *destruction*, the value attained by S is called **the Rupture modulus,** or modulus of rupture.

11. It will be noticed that the strengths of similar beams of any shape, and those of rectangular beams, whether similar or not, are directly proportional to the product, width $\times$ square of depth. See ¶ 63.

12. When the stress, S, upon the extreme fibers, is = the elastic limit of the material, failure is imminent. The permissible unit stress is usually taken as not more than half the elastic limit, and the safe load is that under which S does not exceed the permissible unit stress.

13. The same quantity of material that composes a solid beam, Fig. 2, would present greater resistance to bending or breaking if it were cut in two lengthwise along the neutral surface, *n n*, and converted into top and bottom chords of a truss; because, first, the *leverage* with which the resistance acts is thus greatly increased; and, second, the depths of the chords are so small, compared with their distances from the neutral axis, that their fibers may be assumed to act *unitedly* and *equally*. Hence, practically, *all* the fibers in the upper chord must be crushed, or *all* those in the lower pulled apart, *at the same instant*, before the truss can give way; whereas, in the solid beam, the extreme upper or lower fibers yield first; then those next to them, and so on, one after the other.

Moment of Inertia.

14. Unlike the moment of a force, which is the product of a force and a distance, the moment of inertia, being the sum of the products of areas of fibers by the squares of their distances from the neutral axis, is a purely *geometrical* quantity. Thus, the moment of inertia of a given section depends solely upon the dimensions and shape of that section, and is independent of the material and the span of the beam and of the manner in which it is supported or loaded.

Unit of Moment of Inertia. The moment of inertia of a figure being the product of an area by the square of a distance, its unit is the fourth power of a unit of length. Thus, in a rectangle 3 ins. wide and 4 ins. deep, $I = \frac{b\,d^3}{12} = \frac{3 \times 64}{12} = \frac{192}{12} = 16$ biquadratic inches = 16 inch^4.

In a rectangle 1 inch wide and 6 ins. deep, $I = \frac{1 \times 6^3}{12} = 18$ inch^4.

15. Comparing similar sections of any shape, their moments of inertia are proportional to the product, breadth $\times$ cube of depth. Compare ¶ 11.

16. The following illustrated table, pp. 469–471, gives, for several figures of frequent occurrence,

(1) I = the moment of inertia $= \Sigma\, t^2 a$;

(2) T = the distance from the neutral axis to the farthest fiber;

(3) X = the section modulus $= \frac{I}{T} = \frac{\Sigma\, t^2 a}{T} = \frac{R}{S} = \frac{M}{S}$;

(4) A = the area of the cross-section.

17. In sections where the distance from the neutral axis to the lowermost fiber, and the corresponding section modulus, differ from those (T and X) pertaining to the uppermost fiber, those corresponding to the lowermost fiber are distinguished as T′ and X′ respectively.

18. In each figure the neutral axis is indicated by a horizontal line crossing the section.

19. The moment of inertia of any figure, about its neutral axis, is the sum of the moments of inertia of its several parts, about that same axis.

20. Let I = the moment of inertia of the entire figure about its neutral axis, *o o*;

i = the moment of inertia of any part, about the neutral axis, *o o*, of the entire figure;

m = the moment of inertia of that part, about its own neutral axis;

a = the area of that part;

t = the distance of its center of gravity from the neutral axis, *o o*, of the entire figure.

Then $I = \Sigma i$; and $i = m + a t^2$.

21. Thus, in Fig. 4,

$$i_1 = \frac{B D^3}{12} + B D t_1^2;$$

$$i_2 = \frac{b d^3}{12} + b d t_2^2;$$

and $I = i_1 + i_2$.

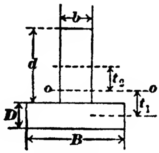

Fig. 4.

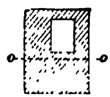

Fig. 5.

22. Hence, in any hollow section, as in the hollow rectangle, Fig. 5, let I' = the moment of inertia of the whole figure (including both the shaded and the unshaded rectangles), i = that of the missing or unshaded rectangle, and I = that of the shaded portion; all referred to the neutral axis, *o o*, of the *shaded portion*. Then $I = I' - i$.

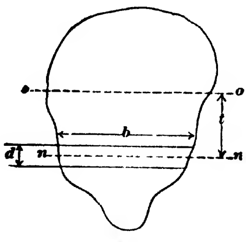

Fig. 6.

23. In the case of an irregular section, as Fig. 6, let the section be divided into numerous strips, parallel to the neutral axis and narrow enough to be considered as rectangular; and proceed as in ¶¶ 19 to 21.

24. The narrower the strips are taken, the less m becomes. If the strips be taken so narrow (relatively to the depth of the section) that m may be neglected, then $I = \Sigma\, t^2\, a$, as in ¶ 10. The strips need not be of uniform width.

The Section Modulus.

25. Definition. If the resisting moment, $R = \frac{S}{T} \cdot \Sigma\, t^2\, a$, be divided by the unit stress, S, in the extreme fibers, the quotient, $X = \frac{R}{S} = \frac{\Sigma\, t^2\, a}{T} = \frac{I}{T}$, is called the Section Modulus. This, like the moment of inertia, ¶¶ 14, etc., is a purely *geometrical* quantity, depending solely upon the dimensions and shape of the section, and being independent of the material, of the span, and of the manner of loading.

26. Having the section modulus, X, we have only to multiply it by the unit stress, S, in the extreme fibers, in order to obtain the resisting moment, R, or $R = S\, X$.

27. Multiplying the section modulus, X, by the distance, T, from the neutral axis to the farthest fibers, we obtain the moment of inertia, I; or, $I = T\, X$.

28. The section modulus is usually given in tables of rolled beams, channels and shapes. See tables of Carnegie Beams, etc.

Loading. Strength.

29. The following illustrated table gives (1) the max moment, M, corresponding to a given load, W; and (2) the load, W,* corresponding to a given unit stress, S, for different conditions of support and of loading. In this table,

M = maximum bending moment;
R = M = resisting moment of cross section;
W = the total extraneous load* on the beam, whether concentrated at one point (as shown) or uniformly distributed over the span;
l = the span;
S = the unit stress, in the fibers farthest from the neutral axis, due to the extraneous load, W, *
T = the distance from the neutral axis to the farthest fibers;
I = the moment of inertia.

In rectangular beams,

b = breadth;
d = depth;
I = moment of inertia $= \frac{b\, d^3}{12}$;
$n = \frac{W\, l}{S\, b\, d^2}$.

Of the two diagrams under each loading, the first represents the moments, and the second the shears, in the several parts of the span.

30. If S = the permissible unit fiber stress, then, in the foregoing formulas, W = the permissible extraneous load.*

31. It will be noticed that the strengths of similar beams are proportional to their values of $\frac{b\, d^2}{l}$; *i. e.*, the strengths of beams of similar cross-sections are directly proportional to their breadths and to the squares of their depths, and inversely proportional to their spans.

* The beam is here supposed to be without weight. See ¶¶ 42 etc.

		$S = \frac{WTl}{12I}$	$S = \frac{WTl}{bd^3} = \frac{Wl}{2bd^2}$	

Symbols in Table Opposite.

M = maximum bending moment;
R = M = resisting moment of cross section;
S = unit stress, due to W, in the extreme fibers;
T = distance from the neutral axis to the extreme fibers;
I = moment of inertia;
W = load; l = span.
In rectangular beams, b = breadth; d = depth; $n = \frac{W\,l}{S\,b\,d^2}$; $W = n\,S\,\frac{b\,d^2}{l}$.

Beam 1 Inch Square, 1 Foot Span.

32. In a beam, 1 inch square and 1 foot (12 inches) span, supported at both ends, we have, for the extraneous center load:*

$$W' = S \cdot \frac{2\,b\,d^2}{3\,l} = \frac{n\,S\,b\,d^2}{l} = S \cdot \frac{2}{3 \times 12} = \frac{S}{18}; \text{ and } S = 18\,W'.$$

33. For any other rectangular beam, let L = the span in feet. Then the extraneous center load,* W, required to produce the same unit stress, S, in the extreme fibers, is

$$W = W' \frac{b\,d^2}{L}.$$

34. Thus, for yellow pine, let S = the permissible unit stress = 1620 lbs. per sq. in. Then, for a beam 1 inch square, 1 foot span, supported at both ends and loaded at center, the permissible load,* W', is

$$W' = \frac{n\,S}{12} = \frac{S}{18} = \frac{1620}{18} = 90 \text{ lbs.},$$

and, for a joist, 3 × 12 ins., 20 ft. span; the permissible extraneous * center load is

$$W = W' \frac{b\,d^2}{L} = 90 \times \frac{3 \times 144}{20} = 1944 \text{ lbs.};$$

and the permissible extraneous uniform load is = 2 W = 2 × 1944 = 3888 lbs.

35. If the load, W the span, L, and the coefficient, W', are given, we have $b\,d^2 = \frac{W\,L}{W'}$. Thus, in the case of the yellow pine joist, mentioned in ¶ 34, of 20 ft span, with a uniform extraneous* load, where 2 W = 2 × 1944 = 3888 lbs., we have $b\,d^2 = \frac{W\,L}{W'} = \frac{1944 \times 20}{90} = 432$.

36. Then, if either b or d is given, the other is easily found. If not, assign to either of them, an arbitrary value. Thus, if $b = 6$, we have $d^2 = \frac{432}{6} = 72$; and $d = \sqrt{72}$ = say $8\frac{1}{2}$. With $b = 3$, $d^2 = 144$, and $d = 12$.

37. With the slide rule, in the foregoing example, place the runner at 432, and, assuming $b = 6$, place 1 (or 10) on the slide, opposite 6 on the rule Then, in the scale of square roots, on the slide, opposite 432 on the rule, will be found 848 and 268. The former of these represents the desired root, and we take 8.5 as a sufficient approximation.

38. If the relation, S = 18 W, held beyond the elastic limit, and if W' = the center *breaking* load, in lbs., on a beam of any material, 1 inch square, 1 ft. span, supported at each end; then, for any other beam of the same material, and of breadth b ins., depth d ins., and span L ft., the center *breaking* load would be $W = W' \frac{b\,d^2}{L}$.

39. Notwithstanding the defective basis of this method, as applied to loads beyond the elastic limit, its simplicity renders it very convenient, and it is much in use. See the following table of values of W', and example, ¶ 40.

---

* The beam is here supposed to be without weight. For the weight of the beam itself, see ¶¶ 42, etc.

Center Breaking Loads, W', in Pounds, for Beams 1 Inch Square, 1 Foot Span, Supported at Each End.

40. Example. In the yellow pine joist of ¶¶ 34 and 36, 3 × 12 ins., 20 ft. span, we have, from the table, W′ = say 500 lbs. Hence

Center breaking load * $W = W' \frac{bd^2}{L} = \frac{500 \times 3 \times 144}{20} = 10{,}800$ lbs., or about 5.5 times the permissible load, found, by means of the permissible unit stress, in ¶ 34.

Dimensions.

41. Since $W = n\,S\,\frac{bd^2}{l} = W'\,\frac{bd^2}{L}$, and $W' = \frac{n\,S}{12}$, we have *

$$\textbf{Breadth} = b = \frac{W\,l}{n\,S\,d^2} = \frac{W\,L}{W'\,d^2};$$

$$\textbf{Depth} = d = \sqrt{\frac{W\,l}{n\,S\,b}} = \sqrt{\frac{W\,L}{W'\,b}};$$

where W = extraneous load * required;
W′ = extraneous load on beam 1 inch square, 1 ft. span;
n = coefficient from last column of table = $\frac{W\,l}{S\,b\,d^2}$;
S = unit fiber stress;
l = span in inches;
L = span in feet.

Weight of Beam Considered as Load.

42. For simplicity we have hitherto regarded our cantilevers and beams as having no weight of their own; and, in beams of the moderate dimensions usually employed in buildings, their own weight, w, is so small, in comparison with their loads, W, that it may often be safely neglected; but in larger beams it must generally be taken into account. The loads, found as above, with S = greatest permissible unit stress, must then be regarded as including not only the extraneous load, W, but also the weight, w, of the beam itself, for a length = span.

43. If the beam is prismatic,—*i. e.*, of uniform cross-section,—its weight, w, acts as a uniformly distributed load, and we have, for the extraneous load, W, in the case of a concentrated center load on a beam, or of a concentrated load at the end of the span, l, in cantilevers,

$$W = \text{whole load} - \frac{w}{2};$$

in the case of a uniform load,

$$W = \text{whole load} - w.$$

44. In finding the breadth or the depth of a rectangular beam, required to carry a given load with a given span and given unit stress, we may provide for the weight by successive approximations. Thus,

45. To find the breadth, b, required for a beam of given depth, d. Neglecting the weight, w, of the beam, find the first approximate breadth, b, by the formulas in ¶ 41, for the extraneous load, W. Next, calculate the weight, w, of a beam with width, b, treat said weight as a uniform load; and, by the same formulas, find the additional breadth, b', required to carry this additional load, w. Then $b + b'$ = a second approximate breadth. If necessary, find the weight, w', of a beam of breadth, b', and, from this, a second additional breadth, b'', required to carry it. Then $b + b' + b''$ = a third approximate breadth, and so on.

46. To find the depth, d, required for a beam of given breadth, b, find a first approximate depth, d, by the formula, ¶ 41, for the extraneous load, W. Find the weight, w, of a beam of that depth; and again apply the formula, using (in place of W) W + w if W is a uniform load, or W + $\frac{w}{2}$ if W is a concentrated load. The depth, d', so found, is a second approximation. We may again apply the formula, as before, using the weight, w', of beam of depth d'; or, more simply, increase the breadth, as in ¶ 45.

---

* The beam is here supposed to be without weight. See ¶¶ 42, etc.

47. In practice, beams of rectangular section are almost always of timber and such beams are economically obtainable only in certain commercial sizes. Hence, the second approximation will usually be all that is required.

Strengths and Weights of Similar Beams of Different Dimensions. Comparison between Models and Actual Structures.

48. In any given beam, let W_1 = the load causing any given unit stress, S. Then, $W_1 = \frac{n\,S\,b\,d^2}{l}$ (for n, see table, p. 474); and, in any similar beam, of a times the breadth, depth and span, the corresponding load, $W = \frac{n\,S\,a\,b\,a^2\,d^2}{a\,l}$. Hence, the ratio of their *loads* is $\frac{W}{W_1} = a^2$; or $W = a^2\,W_1$; but the ratio of their *weights* is $\frac{w}{w_1} = \frac{ab\;ad\;al}{b\;d\;l} = a^3$; or $w = a^3\,w_1$.

49. In other words, comparing one beam with another, of a times its breadth, depth and span, their *strengths* are as the *squares* of their respective dimensions; but their *weights* are as the *cubes* of those dimensions.

50. Hence, if a model of a beam will just break under a uniform load (including its own weight, w) = 2, 3 or 4, etc., times its own weight, then a beam of similar cross-section, but of 2, 3 or 4, etc., times its breadth, depth and span, will just break under its own weight alone.

Horizontal Shear. See also ¶¶ 119–122.

51. When (Figs. 7 and 8) deflection occurs in a cantilever or beam composed of separate horizontal layers, like a pile of loose boards, the several layers slide upon each other; but, if they are firmly joined together, or otherwise prevented from sliding, they exert, upon each other, a horizontal shearing force. In any section, this force diminishes from a maximum, at the neutral surface, $n\,n$, to zero, at the top and bottom of the section.

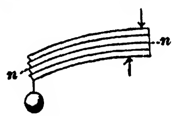

Fig. 7.

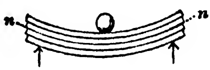

Fig. 8.

52. In any section of a rectangular beam, the maximum horizontal shear, per unit of neutral surface, is

$$H = \frac{3\,V}{2\,b\,d},$$

where V = the vertical shear in the section, and b and d = the breadth and the depth of the section, respectively.

In words, the unit horizontal shear, at any point, is directly proportional to the vertical shear at that point. Hence, the horizontal shear diagram is similar, in character, to the vertical shear diagram; but is opposite in sense, positive vertical shear corresponding to negative horizontal shear.

53. If the horizontal shear is resisted by a fastening applied at only one point, said fastening must be made sufficiently strong to resist the *sum of all* the horizontal shears between such point and that where the shear is = 0.

54. In Fig. 9, diagrams (*b*) and (*c*) show respectively the moments and the vertical shears due to concentrated and distributed loads on a beam as shown; and, in Fig. (*d*), each ordinate represents the force which must be applied, at the corresponding point, in order to resist the sum of all the horizontal shears between that point and the point of zero shear. Ordinates above a zero line indicate positive moments or shears, and vice versa. In *positive* moments, the segment to the *left* of a

section tends to turn *clockwise*. In *positive* shears, the *left*-hand segment tends to slide *upward* or the *upper* segment to slide toward the *right*. Between a and c, between c and d, between g and h, and between h and b, all the diagrams are straight lines, Figs. (b) and (d) being inclined, and Fig. (c) horizontal. At c and at h, Figs. (b) and (d) change their inclination, and Fig. (c) shifts its position. Between d and f, and between f and g (*i. e.*, under the distributed load), Figs. (b) and (d) are parabolic curves, and Fig. (c) shows inclined straight lines. At f, Figs. (b) and (d) change curvature, and Fig. (c) shifts its position. At e, the point of maximum moment, Figs. (c) and (d) change signs. See Relation between Moment and Shear, Statics, ¶¶ 359 to 368.

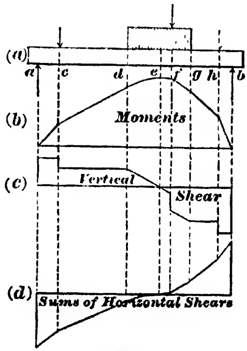

Fig. 9.

55. Inasmuch as the horizontal shear is a resistance to bending, its neglect, in the common theory of beams, as heretofore explained, is in general on the side of safety. But, in beams composed of horizontal layers, means must be provided for its transmission from one layer to the next.

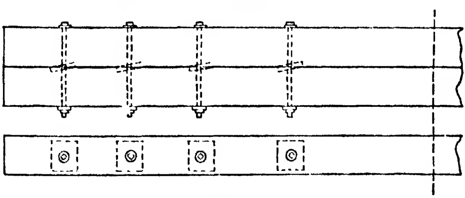

Fig. 10.

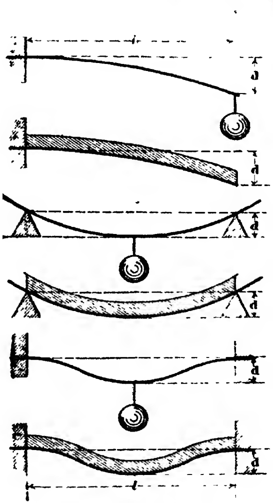
56. Thus, deep wooden beams, Fig. 10, are frequently built up of two or more timbers, one above the other. In order to prevent deflection, due to the sliding of these timbers upon each other, blocks are inserted between them at intervals, as shown, or the adjacent sides of the timbers are so notched as to interlock. In either case, the timbers are tightly bound together. The blocks or notches then serve to transmit the horizontal shear from one timber to the other. In Fig. 10 the blocks are more numerous near the ends of the span, as required by the diagram of horizontal shear, Fig. 9 (d).

DEFLECTIONS OF BEAMS OF UNIFORM CROSS SECTION THROUGHOUT. (For signification of letters, see opposite.)



If the beam is	Deflection d, in inches, caused by extraneous load.	Deflection d, in inches, caused by weight of beam	Deflection d, in inches, caused by weight of beam and load	Extraneous load for a given deflection (weight of beam neglected.)

Deflections.

57. The opposite table gives the **deflections** within the elastic limit of any *prismatic* beam (beam of uniform cross section throughout) **under different arrangements of support and of load;** also (in the last column) the *extraneous* **load which will produce a given deflection,** without assistance from the weight of the beam itself. All the formulæ are based upon the assumption that the increase of deflection is proportional to increase of load.

The letters signify as follows:

d = deflection of beam, in inches (see Figs).
W = weight of extraneous load in pounds
w = " " clear span of beam, in pounds.
l = clear span of beam, in inches (see Figs).
E = modulus of elasticity of the material of the beam, in lbs. per sq. inch.
I = moment of inertia of the cross section of the beam, in biquadratic inches. See "Unit of Moment of Inertia," p. 468.

From the principles embodied in the opposite table, we find that in beams of similar cross section and of the same material, and within the elastic limit, the loads and deflections (neglecting the weight of the beam itself) are as follows:

With the same	The deflections under a given extraneous load are
span	inversely as the breadths and as the cubes of the depths
" and breadth	" " " " "
" " depth	" " breadths
breadth " "	directly " cubes of the spans

With the same	The extraneous loads for a given deflection are
span	directly as the breadths and as the cubes of the depths
" and breadth	" " " " "
" " depth	" " breadths
breadth " "	inversely " cubes of the spans

Deflection in Terms of Extreme Fiber Stress. In table, p. 474, the load $W = k\,S\,\frac{I}{T\,l}$; where k = a coefficient, as below; S = unit stress in extreme fibers; I = moment of inertia; T = distance from neutral axis to extreme fiber, and l = span. From the table opposite, we have: $W = m\,\frac{d\,E\,I}{l^3}$; where m = a coefficient, as below; d = deflection, and E = modulus of elasticity. Hence, $k\,S\,\frac{I}{T\,l} = m\,\frac{d\,E\,I}{l^3}$; and $d = \frac{k}{m}\cdot\frac{l^2\,S}{E\,T} = \frac{l^2\,S}{E\,T\,c}$; where $c = \frac{m}{k}$.

In a cantilever, loaded at end,	m = 3;	k = 1;	c = 3.
" " " uniformly,	m = 8;	k = 2;	c = 4.
In a beam, supported, and loaded at center,	m = 48;	k = 4;	c = 12.
" " " " " uniformly,	m = 76.8;	k = 8;	c = 9.6
" " fixed, " " at center,	m = 192;	k = 8;	c = 24.
" " " " " uniformly,	m = 384;	k = 12;	c = 32.

Elastic Limit.

58. Under moderate loads, the deflections are practically proportional to the load. When they begin to increase perceptibly faster than the load, the latter is said to have reached the elastic limit, or limit of elasticity. It is generally at this point that the "**permanent set**" first becomes noticeable; i. e., after removal of the load, the beam fails to return to its original unstrained condition, and remains more or less bent. The deflections then also begin to increase *irregularly*; and to continue indefinitely without further increase of load. In short, the beam is in danger. Hence, the actual load *must never exceed* the elastic limit; and should not exceed from one-third to two-thirds of it, according to circumstances.

The limit of elasticity of a beam of any particular form, or material, is **determined by experiment** with a similar beam, as in the case of constants for breaking loads, &c. Thus, load a beam at the center, by the careful gradual addition of small equal loads; carefully note down the deflection that takes place within some minutes (the more the better) after each load has been applied; in order to ascertain when the deflections begin to increase more rapidly than the loads; for when this takes place, the load for elastic limit has been reached.*

It is not the deflections of the *whole* beam that are to be noted, but those of its clear span only. Several beams should be tried, in order to get an *average* constant, for even in rolled iron beams of the same pattern, and same iron, there is a very appreciable difference of strengths and deflections.

Then, to get the constant, using the *total load* applied during the equal deflections, including half the weight of the beam itself,

$$\textbf{Constant for elastic limit} = \frac{\text{Span in feet} \times \text{Total load in lbs.}}{\text{Breadth in inches} \times \text{Square of depth in inches}}$$

The constant, for wooden beams, may be had, near enough for common practice, by taking *one third* of the *breaking* constants in the table, page 476.

Said constant, thus calculated, is the elastic limit of a beam of the given shape and material, 1 inch broad, 1 inch deep, and of 1 foot span, supported at both ends and loaded at the center. To obtain from it the elastic limit of any other beam of the same design ‡ and the same material, similarly supported and loaded, but of other dimensions,

$$\textbf{Elastic limit} = \text{constant} \times \frac{\text{breadth in inches} \times \text{square of depth in inches}}{\text{span in feet}}.$$

"	" " "	" " uniformly,	½

* Of course, in practice, it is frequently difficult to ascertain with precision, when, or under what load, the deflections actually do begin to increase more rapidly than the successive loads. For although *by theory* the deflections are practically equal for equal loads, until the elastic limit is reached, yet in *fact* they are subject to more or less irregularity; for no material composing a beam is perfectly uniform throughout in texture and strength. Hence, instead of regular increase of deflection, we shall have an alternation of larger and smaller ones. Therefore, some judgment is required to determine the final point; in doing which, it is better, in case of doubt, to lean to the side of *safety*. It is assumed always that the load is not subject to jars or vibrations. These would increase the deflections.

† A beam is said to be "fixed" at either end when the tangent to the longitudinal axis of the deflected beam at that end remains always horizontal.

‡ The *shapes* of the two beams need not be *similar*. For instance, the constant deduced from experiments upon any rectangular beam is applicable to any other rectangular beam, whether square or oblong.

The Elastic Curve.

59. When a cantilever, Fig. 1, or a beam, Fig. 2, supported or fixed in any manner, bends, under the action of any load, the neutral surface, $n\ n$, forms a curve, such that, at any section,

$$R = \frac{E\,I}{M} = \frac{I\,S}{M\,k};$$

where

- R = the radius of curvature, at the section;
- M = the bending moment, at the section;
- I = the moment of inertia of the section;
- E = the elasticity coefficient of the material, $= \frac{S}{k}$;
- S = any unit stress within the elastic limit;
- k = the unit "stretch" (elongation or compression) produced by S in the given material.

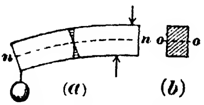

Fig. 1 (repeated).

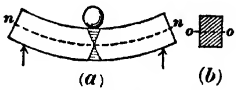

Fig. 2 (repeated).

The Deflection Coefficient.

60. Definition. The deflection coefficient, for any given material, is the deflection, in inches, of a beam, of that material, 1 inch square and of 1 foot span, supported at each end, and carrying, at its center, an extraneous load of 1 lb. — ⅝ w', where w' = weight of clear span of beam alone, in lbs.

61. Let y = the deflection coefficient for any given material. Then, in any rectangular beam, of the same material, with center load or uniform load, let

- b = the breadth, in inches;
- d = the depth, in inches;
- L = the span, in feet;
- w = the weight, in lbs., of the clear span of the beam itself;
- W = center load + ⅝ w;
  = ⅝ (uniform load + w).

Then, in the given beam,

Deflection $= Y = y\,\frac{W\,.\,L^3}{b\,.\,d^3}$; **Breadth*** $= b = W\,.\,\frac{L^3\,.\,y}{d^3\,.\,Y}$;

Load $= W = Y\,.\,\frac{b\,.\,d^3}{L^3\,.\,y}$. **Depth*** $= d = L\,\sqrt[3]{\frac{W\,y}{b\,Y}}$.

62. The deflection coefficient, y, for any given material, is obtained by experiment, thus: At the center of any rectangular beam, of the given material, placed horizontally upon two supports, at any convenient and known distance apart, place any load that is within the elastic limit, and measure the resulting deflection, Y. Let W = the extraneous center load + ⅝ w, where w = the weight, in lbs., of the clear span of the beam itself. Then the deflection coefficient is

$$y = Y\,.\,\frac{b\,.\,d^3}{W\,.\,L^3};$$

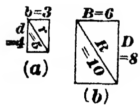
where b and d = the breadth and depth, in inches, and L = the span, in feet, of the experimental beam.

---

* In calculating the breadth or the depth, if it is necessary to provide for the weight of the beam itself, we first let W = the extraneous load only, and then proceed by successive approximations, as in ¶¶ 45 and 46, remembering, however, that in the case of deflections, 5-8 of the weight of each additional section is to be taken as equivalent center load, and not 1-2 as in the case of strengths.

63. The ratio between any two homologous lines, in any two similar figures, is constant. Hence, in determining or using coefficients, whether for strength or for deflection, by comparing beams of similar sections but of different sizes, we may use any two homologous lines in place of the two breadths, or in place of the two depths, or the same line may be taken in place of both breadth and depth.

Thus, in Figs. 11, $B/b = D/d = R/r = 2$.



Figs. 11.

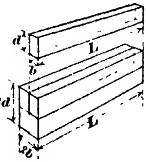


Fig. X.

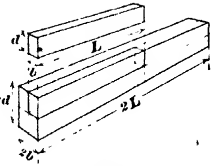

Fig. Y.

Hence,

$$\frac{B\,D^2}{b\,d^2} = \frac{384}{48} = 8 = 2^3 = \frac{R\,R^2}{r\,r^2} = \frac{1000}{125} = 8 = 2^3;$$

Also,

$$\frac{B\,R^2}{b\,r^2} = \frac{6 \times 100}{3 \times 25} = \frac{600}{75} = 8 = 2^3.$$

Also,

$$\frac{B^3\,D}{b^3\,d} = \frac{1728}{108} = 16 = 2^4 = \frac{R^3\,R}{r^3\,r} = \frac{10{,}000}{625} = 16 = 2^4$$

63 a. From the foregoing and from ¶ 31, p. 473, it follows that, with *similar cross sections* but *equal spans*, Fig. X, the strengths are proportional to the *cubes* of any homologous lines in the two sections, but, with beams similar *in all respects, including span*, Fig. Y, the strengths are as the *squares* of any homologous lines in the two sections; *i. e.*, as the *areas* of the two sections.

64. Deflection coefficient for beams of rectangular cross section. See ¶¶ 60, 61. Beam 1 inch square, 12 ins span. W (= cen load + ⅝ × weight of clear span) = 1 pound. From p 480, we have,

$$\text{Defl coeff} = \text{defl, } y, \text{ in ins, at cen,} = \frac{L^3\,W}{48\,E\,I} = \frac{12^3 \times 12}{48\,E} = \frac{432}{E}.$$

65. Caution. The deflections of timber of the same kind vary greatly with the degree of seasoning, the age of the tree, the part from which the beam is cut, etc. In our own experiments on good pieces, well seasoned, on which the loads were allowed to remain for months, less than 2 per cent. of the breaking load produced a permanent set in a few months. Several of the sticks bore their breaking loads for months before actually giving way. The vibrations and jars, to which all structures are exposed, in time increase the deflections.

66. Eccentric Concentrated Loads. Let Y, Fig. 12 (*a*), be the deflection, at the center of the span (*i. e.*, at the point of application of the load) of a beam supported at each end, due to a load, W, within the elastic limit, at the center of the span. Then, if the same load, W, be placed eccentrically upon the same beam, as in Fig. 12 (*b*), the deflection, Y′, at the point, *c*, of application of the load, and due to the load, W, is

$$Y' = Y\,\frac{16\,m^2\,n^2}{l^4};$$

where

l = the span;

m and n = the segments into which the load divides the span.

67. Uniform Loads. Let Y be the deflection, due to any central extraneous load (within the elastic limit), on a beam supported at each end. Then the deflection, Y′, of the same beam, due to the same load uniformly distributed over the span, is

$$Y' = \frac{5}{8}\,Y.$$

68. Inclined Beams. If the beam is inclined, use the horizontal projection of its span, in place of the span, l, in determining its deflections.

69. Cylindrical Beams. Let Y be the deflection of a square beam under any given load. Then, for a cylindrical beam whose diameter = side the square, the deflection, under the same load, is = 1.698 Y.

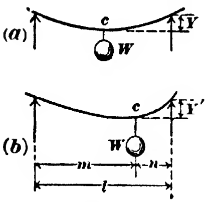

Fig. 12.

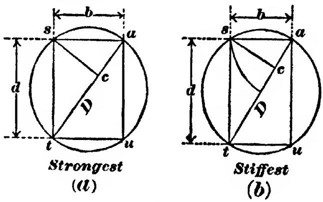

Fig. 13.

70. Figs. 13 (*a*) and (*b*) show, respectively, the strongest and the stiffest rectangular sections which can be cut from a given cylindrical log, of diameter, D. In the strongest section Fig. (*a*), $a\,c = \frac{D}{3}$, and $b = \sqrt{\frac{1}{3}\,D^2}$. In the stiffest section Fig (*b*), $a\,c = \frac{D}{4}$, and $d = \sqrt{\frac{3}{4}\,D^2}$.

71. Maximum Permissible Deflection. Under even a perfectly safe load, a beam may bend too much for certain purposes. Thus, to prevent the cracking of the plaster of ceilings, it is usual to limit the deflection of beams to $\frac{\text{span}}{360} = \frac{1}{30}$ inch per foot of span = 3⅓ ins. per 100 ft. In long lines of shafting, for machinery, the deflection is usually limited to $\frac{\text{span}}{1200}$ = 1 inch per 100 feet of span; in highway bridges to $\frac{\text{span}}{640} = \frac{3}{16}$ inch in 10 ft.; in railroad bridges to $\frac{\text{span}}{1600} = \frac{3}{4}$ inch per 100 feet.

72. Let Y = the maximum permissible deflection, in inches per foot of span, in any given case;
y = the deflection coefficient, ¶¶ 60, etc.
L = the clear span of the beam, in feet;
w = the weight of the clear span of the beam, in lbs.;
W = the center load + ⅝ w;
= ⅝ (uniform load + w).

Then, Y L = the deflection, in inches, for the whole span, L, and we have, for the permissible load, W, and the required breadth, b, and depth, d, for a rectangular beam (see ¶ 61):

$$\textbf{Load} = W = \frac{Y\,L\,b\,d^3}{L^3\,y} = \frac{Y\,b\,d^3}{L^2\,y};$$

$$\textbf{Breadth}^{*} = b = W \cdot \frac{L^2\,y}{d^3\,Y};$$

$$\textbf{Depth}^{*} = d = \sqrt[3]{W \cdot \frac{L^2\,y}{b\,Y}}.$$

* See foot-note to ¶ 61.

Suddenly Applied Loads.

73. Suppose a load to be applied to a flexible beam suddenly, though without falling or jarring; as, for instance, if it be supported by a cord which allows it just to touch the beam without bearing upon it, and the cord be then suddenly cut in two. The deflection of the beam, in such a case, is theoretically twice as great as when the same load is applied gradually, as by very slowly relaxing the cord, or by dividing the weight into small fragments and applying them at intervals, one by one. See ¶¶ 35 etc, under Strength of Materials. Hence the strength of the beam (within the elastic limit) is much more severely taxed in the former than in the latter case. A heavy train, coming very rapidly upon a bridge, presents a condition intermediate between the two.

Cantilevers and Beams of Uniform Strength.

74. For equilibrium, the resisting moment, R, of any section, must balance the bending moment, M, at that section. Or,

$$\frac{S}{T} \cdot I = M; \text{ or, } S = M \cdot \frac{T}{I};$$

where S = unit stress in extreme fibers;
T = distance from neutral axis to extreme fibers;
I = moment of inertia of section.

75. In a beam of uniform cross-section, therefore, since T and I are uniform throughout the span, the unit stress, S, on the extreme fibers, varies with the bending moment, M. For uniform strength against bending moments, the cross-section must so vary that $\frac{T}{I}$ shall be inversely proportional to M, in order that S may remain constant.

76. The following table shows, in elevation and in plan, the theoretical shapes of rectangular cantilevers and beams of uniform strength against bending moments, under concentrated and uniform loads. In practice, some of these shapes would of course have to be made stronger near their ends, in order to provide a sufficient section to resist shear.

77. Notwithstanding the reduction in material which would be effected, by using beams of uniform strength, their use is seldom economical, except in the case of cast iron. In timber, the material removed would not be saved; and, in steel, the saving in material would often be offset by the cost of additional labor.

Moreover, it will be noticed that the **deflections** of beams of uniform strength, under a given loading, are considerably greater than those of beams of uniform cross-section.

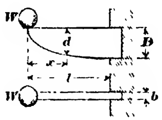
In the table,

W = concentrated load;
w = uniform load per unit of span;
l = span;
x = distance from a support to any given section;
d = depth of beam at that section;
b = breadth of beam at that section;
D = maximum depth of beam;
B = maximum breadth of beam;
S = unit stress in extreme fibers;
E = elasticity coefficient = $\frac{\text{unit stress}}{\text{unit stretch}}$;
Y′ = deflection, due to extraneous load, in beam of uniform strength;
Y = deflection, due to extraneous load, in beam of uniform cross-section = maximum cross-section of beam of uniform strength

Cantilevers of Rectangular Cross-section and of Uniform Strength. Profiles, Plans and Deflections.

For symbols, see ¶ 77.

Concentrated Load, = *W*, at end.

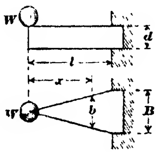


Breadth, b, constant

Profile, parabola, with vertex at load.

$$d = \sqrt{\frac{6\,W\,x}{S\,b}}, \quad Y' = \frac{8\,W\,l^3}{E\,b\,D^3} = 2\,Y,$$

D = Maximum depth.

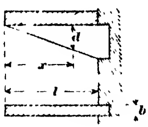


Depth, d, constant.

Plan, triangle.

$$b = \frac{6\,W\,x}{S\,d^2}; \qquad Y' = \frac{6\,W\,l^3}{E\,B\,d^3} = \frac{3}{2}\,Y.$$

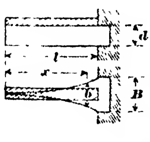
Uniform Load, = *w* per unit of span.



Breadth, b, constant

Profile, triangle

$$d = x\sqrt{\frac{3\,w}{S\,b}}$$



Depth, d, constant

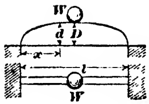
Plan, two parabolic curves, with vertices at free end.

$$b = \frac{3\,w\,x^2}{S\,d^2}, \qquad Y' = \frac{3\,W\,l^3}{E\,B\,d^3} = 2\,Y.$$

Beams of Rectangular Cross-section and of Uniform Strength. Profiles, Plans and Deflections.

For symbols, see opposite page.

Concentrated Load, = *W*, at center.

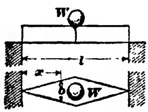


Breadth, *b*, constant.

Profile, two parabolic curves, with vertices at supports.

$d = \sqrt{\frac{3\,W\,x}{S\,b}}$ D at center of span

$Y' = \frac{W\,l^3}{2\,E\,b\,D^3} = 2\,Y$

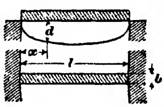


Depth, *d*, constant B = maximum width

Plan, two triangles

$b = \frac{3\,W\,x}{S\,d^2}$, $Y' = \frac{3\,W\,l^3}{8\,E\,B\,d^3} = \frac{3}{2}\,Y$

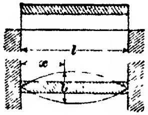
Uniform Load, = *w* per unit of span.



Breadth, *b*, constant

Profile, ellipse or semi-ellipse

$d = \sqrt{\frac{3\,w}{S\,b}\,(\,l\,x - x^2\,)}$



Depth, *d*, constant

Plan, parabolas with vertices at center of span

$b = \frac{3\,w}{S\,d^2}\,(\,l\,x - x^2)$

Symbols in table opposite:

W = concentrated load; w = uniform load per unit of span;
l = span; x = dist from a support to given sec;
d = depth of beam at that sec; b = breadth of beam at that sec;
D = maximum depth of beam; B = maximum breadth of beam;
S = unit stress in extreme fibers;
E = elasticity coefficient = $\frac{\text{unit stress}}{\text{unit stretch}}$;
Y′ = deflection due to extraneous load in beam of uniform strength;
Y = deflection, due to extraneous load, in beam of uniform cross-section = max cross-section of beam of uniform strength.

Continuous Beams. See also ¶¶ 134–6.

78. A continuous beam is one which rests upon more than two supports.

79. The resistances and deflections of continuous beams, like those of beams with fixed ends, are determined by means of the elastic curve, using the calculus. The more important facts, thus deduced, are indicated in Fig. 14 and illustrated table, ¶ 89.

80. Fig. 14 represents the general character of the deflections, and the variations of the moments and of the shears, in uniformly loaded continuous beams.

81. Moments. Fig 14 (*b*). Ordinates drawn *above* the zero line, *a′ b′*, represent *positive* moments, or those where the segment of the beam, to the left of any section, tends to revolve *clockwise;* and vice versa.

82. At each end of the beam, at one point, *i* (called the inflection point, or point of contrary flexure) in each end span, and at two such points in each remaining span, the moment is zero.

83. At another point, *m*, in each span, the positive moment reaches a maximum for that span; while the negative moments reach their maxima at the supports. Both the positive and the negative moments vary in the different spans; but, if the spans are equal, then the moments, at any two points equidistant from the center of the whole beam, are equal.

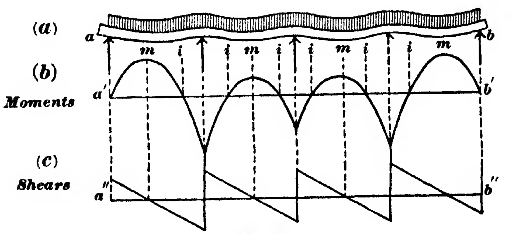


Fig. 14.

84. The moment diagram, between each support and the point, *m*, of maximum positive moment on either side of it, is a semi-parabola, with its apex at *m*.

85. Shears. Fig. 14 (*c*). Ordinates drawn *above* the zero line, *a″ b″*, represent *positive* shears, or those in which the *left*-hand segment, at any section, tends to slide *upward* past the *right*-hand segment; and vice versa.

86. At the point, *m*, of maximum moment, in each span, the shear is zero. Between each such point and the next support on the left, the shear is positive, and vice versa.

87. At each support the shear suddenly changes, by an amount = the reaction of the support.

88. The shear diagram is a series of straight lines.

Continuous Beams.

$m\,w\,l^2$ — Moment.
$v\,w\,l$ — Shear.
$a\,l$ — Distance from left support of any span to point of maximum positive moment in that span.
$x\,l$ — Distance from any left support to inflection point.
w — Load per unit of span.
l — Span.

Number of Spans	Number of Supports	m =	a =	x =	v =
2	3	0; + 0.0703; − 0.125	0.375	0.75	0; + 0.375; − 0.625; + 0.625
3	4	0; + 0.08; − 0.10; + 0.025	0.4; 0.5	0.8; {0.276, 0.724}	0; + 0.4; − 0.6; + 0.5
4	5	0; + 0.0772; − 0.1071; + 0.0364; − 0.0714	0.3930; 0.5357	0.7860; {0.2659, 0.8055}	0; + 0.3929; − 0.6071; + 0.5357; − 0.4643; + 0.4643
5	6	0; + 0.0779; − 0.1053; + 0.0332; − 0.07895; + 0.0461	0.3947; 0.5264; 0.5	0.7894; {0.2680, 0.7830}; {0.1964, 0.8036}	0; + 0.3947; − 0.6053; + 0.5263; − 0.4737; + 0.5000

89. The illustrated table opposite represents the conditions theoretically existing in uniformly loaded continuous beams of from two to five equal spans. Only the left half of each such beam is shown, the right half being symmetrical with it.

90. The Figs. show the amount of the maximum positive moment in each span, that of the negative moment at each support, and the shear on each side of each support.

91. The Figs. show, also, the coefficient, a, for the distance, $a\,l$, from the left support of each span to the point of maximum moment in that span; and the coefficient, x, for the distance or distances, $x\,l$, from the same support to the inflection point or points in that span. In each central span, the sum of the two values of x is = 1. In each end span, $x = 2\,a$.

92. In each central span, the point of maximum positive moment is at the center of the span. In other words, the deflection in that span is symmetrical, or $a = 0.5$.

93. The numerical sum of the two shears, one on each side of a support, is = the reaction of that support. At each central support, the shears, on its two sides, are equal.

In the Figs.,

w = load per unit of span;
l = span;
m = the coefficient for moment;
$m\,w\,l^2$ = moment;
v = the coefficient for shear;
$v\,w\,l$ = shear;
a = the coefficient for distance to point of maximum moment;
$a\,l$ = distance from left support of any span to point of maximum positive moment in that span;
x = the coefficient for distance to inflection point;
$x\,l$ = distance from left support of any span to either inflection point in that span.

94. Fig. 15 shows the values of m and of v in a uniformly loaded non-continuous beam. Comparing these with the corresponding values in continuous beams, as shown in the illustrated table, opposite, we see that the continuous beam has considerable theoretical advantage. But see ¶ 95.

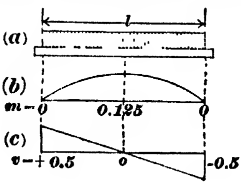

Fig. 15.

95. Certain practical considerations, however, materially reduce these advantages in many cases. Thus, in a continuous railroad bridge of 100 ft. spans, so designed that the maximum deflection shall not exceed $\frac{3}{4}$ inch, a settlement of $\frac{3}{4}$ inch, in an intermediate pier, would deprive the bridge of the support of such pier, and thus practically throw two adjacent spans into one, bringing upon their members stresses far in excess of those for which they were designed. Again, with moving loads, the theoretical advantage may at times be much less than that due to a stationary load and indicated in the illustrated table.

Cross-shaped Beam.*

96. In a cross-shaped beam, Fig. 16, of homogeneous material, loaded at center, let

W = the load;

E = the elasticity coefficient = $\frac{\text{unit stress}}{\text{unit stretch}}$;

Y = the deflection at center;

L, l = the spans of
D, d = the depths of
T, t = the half depths of
I, i = the moments of inertia of
S, s = the unit stresses in the extreme fibers of
P, p = the portions of W borne by
} the two branches respectively.

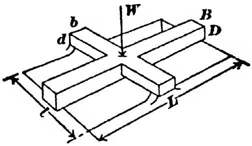

Fig. 16.

Then (see illustrated table, p 480), since the deflection is necessarily the same for both branches,

$$\frac{L^3 P}{E I} = \frac{l^3 p}{E i}; \text{ or}$$

$$\frac{P}{p} = \frac{I \cdot l^3}{i \cdot L^3};$$

and, since $P = 4 \cdot \frac{S}{T} \cdot \frac{I}{L}$, and $p = 4 \frac{s}{t} \cdot \frac{i}{l}$ (see table, p. 474), we have

$$\frac{S}{s} = \frac{D}{d}\left(\frac{l}{L}\right)^2.$$

97. In other words, in order that both branches may be equally strong, their depths (independently of their breadths) must be directly as the squares of their spans, or their spans directly as the square roots of their depths.

---

* F. Reuleaux, "Der Konstrukteur," Braunschweig, 1889. "The Constructor," translated by H. H. Suplee, Philadelphia, 1893.

Transverse Resistance of Flat Plates. For Buckled Plates, see p 1167.

98 The laws governing the resistance of plates, to pressures normal to their surfaces, are but imperfectly understood; and formulas expressing them must be used with caution and as probable approximations.

99. In the following table, the moments are those given, as sufficiently approximate, by Rankine, Civil Engineering, p 544, for **supported edges;** and the stresses are deduced from these moments by means of the formula, $S = M \frac{6}{L\, d^2}$. See symbols, ¶ 101. See formulas for load, in rectangular beams, p 474. For plates with *fixed* edges, see ¶ 100.

A homogeneous oblong plate tends to split along its longer axis.

100. Fixed edges. If M be the moment, and S the maximum fiber stress, for a plate with *supported* edges, and if M_f and S_f be the corresponding values for the same load on the same plate with *fixed* edges, we may assume —

for central load, $M_f = \frac{1}{2} M$; $S_f = \frac{1}{2} S$;
for uniform load, $M_f = \frac{2}{3} M$; $S_f = \frac{2}{3} S$.

See rules for ordinary beams, p 474.

101. In a plate with *supported* edges, let

d = thickness of plate,
w = load per unit of surface;
W = total load,
M = max bending moment;
S = max fiber stress.

In an oblong plate, let
L = longer span;
b = shorter span;
in a square or circular plate, $L = b$;
in a circular plate, r = radius.

Maximum bending moment, M, and maximum fiber stress, S, in plates *supported* at edges. For fixed edges, see ¶ 100.

Central Load.

Plate	Moment, M.	Stress, S.
Oblong $L \not< 1.19\, b$	$\frac{1}{4} W b$	$\frac{3}{2} \frac{b}{L} \frac{W}{d^2}$
$L < 1.19\, b$	$\frac{3}{8} W \frac{L^4 b}{L^4 + b^4}$	$\frac{9}{4} \cdot \frac{L^3 b}{L^4 + b^4} \cdot \frac{W}{d^2}$
Square	$\frac{3}{16} W L$	$\frac{9}{8} \frac{W}{d^2}$*
Circular	$W \frac{r}{\pi}$	$\frac{3}{\pi} \frac{W}{d^2}$*

Uniform Load.

Plate	Moment, M.		Stress, S.	
Oblong	$\frac{1}{8} W \frac{L^4 b}{L^4 + b^4}$	$= \frac{1}{8} w \frac{L^5 b^2}{L^4 + b^4}$	$\frac{3}{4} \cdot \frac{L^3 b}{L^4 + b^4} \cdot \frac{W}{d^2}$	$= \frac{3}{4} \cdot \frac{L^4 b^2}{L^4 + b^4} \cdot \frac{w}{d^2}$
Square	$\frac{1}{16} W L$	$= \frac{1}{16} w L^3$	$\frac{3}{8} \frac{W}{d^2}$*	$= \frac{3}{8} \cdot L^2 \cdot \frac{w}{d^2}$
Circular	$\frac{1}{3} W \frac{r}{\pi}$	$= \frac{1}{3} w r^3$	$\frac{1}{\pi} \cdot \frac{W}{d^2}$*	$= r^2 \frac{w}{d^2}$

102. In a circular plate, uniformly loaded, **deflection** at center $= c \frac{w\, r^4}{E\, d^3}$ where †$c = \frac{2}{3}$ for plates *supported* at edges; $c = \frac{1}{6}$ for plates *fixed* at edges; E = elastic modulus.

---

*Since the stress ($S = M \frac{6}{L\, d^2}$) is proportional to $\frac{W\, L}{L\, d^2}$, the stress, S, under a given *total* load, W, in *square or circular* plates, and in rectangular plates where L/b is constant, is independent of the surface dimensions.

†Compare F. Grashof, Theorie der Elasticitat und Festigkeit, Berlin, 1878, pp 336, 337.

TRANSVERSE AND LONGITUDINAL STRESS COMBINED.

103. Although the combination of longitudinal and transverse stress in the same piece is objectionable, it is often unavoidable. Thus, in a timber roof, the rafters generally act both as columns and as beams.

In such cases, the total unit stress, S, in the extreme fibers, is the sum of the uniform stress, S_c, due to direct compression or tension, and the extreme fiber stress, S_b, due to bending moments only, under the action of the transverse and longitudinal loads combined. Or $S = S_c + S_b$.

Let M_b = the bending moment due to the transverse load; M_c = the bending moment due to longitudinal load, P; and M = the total resultant bending moment, $= M_b - M_c$ when the longitudinal load is tensile; $= M_b + M_c$ when the longitudinal load is compressive.

But $M_c = P\,d$, where P = the longitudinal load, and d = its leverage, = the deflection of the beam, due to all causes; and (see ¶ 57) $d = \frac{l^2 S_b}{E\,T\,c}$; where l = span, S_b = unit stress in extreme fibers, due to bending; E = modulus of elasticity; T = distance from neutral axis to extreme fibers, and c = a coefficient, whose values, for different cases, are given in ¶ 57.

Hence, $M_c = P\frac{l^2 S_b}{E\,T\,c}$; and resultant moment $M = M_b + P\frac{l^2 S_b}{E\,T\,c}$. The resisting moment, R (see ¶ 10), is $= S_b\frac{I}{T}$; and, for equilibrium, R = M.

Hence, $S_b.\frac{I}{T} = M_b + P\frac{l^2 S_b}{E\,T\,c}$; whence we derive, for the extreme fiber stress, S_b, due to bending only, under the action of the transverse and longitudinal loads combined,

$$S_b = \frac{M_b\,T}{I + \frac{P\,l^2}{E\,c}} \quad \text{where the longitudinal stress is tensile}$$

$$S_b = \frac{M_b\,T}{I - \frac{P\,l^2}{E\,c}} \quad \text{where the longitudinal stress is compressive}$$

Besides this we have the unit stress, S_c, due directly to the longitudinal load, P, and $= \frac{P}{A}$, where A is the area of cross-section of the beam. Hence, for the total unit stress, S, in the extreme fibers, we have

$$S = S_c + S_b = \frac{P}{A} + \frac{M_b\,T}{I \pm \frac{P\,l^2}{E\,c}}.$$

When the deflection, d, is negligible, $M_c = 0$; $M = M_b = S_b\frac{I}{T}$; and $S_b = \frac{M_b\,T}{I} = \frac{M\,T}{I}$, as in ¶ 10; and $S = \frac{P}{A} + \frac{M\,T}{I}$. In practice, d is frequently neglected, and this formula used.

DIAGONAL STRESSES IN BEAMS.
Maximum Unit Stresses.

104. When a body (as a bolt) is **under tensile (or comp) stress only**, the tendency of the body, *as regards sections normal to the stress*, is to pull apart (or crush together) in the direction of the stress, or normally to the section, and the entire stress acts normally upon the section; but, *on planes oblique to the stress*, the stress is resolved into two components, one (n) of tension (or comp) normal to the plane, and one (t) tangential to the plane (shearing stress).

105. Under shearing stress alone, the effect, upon a plane *parallel* to & betw the 2 shearing forces, is pure shear; but, upon planes *oblique* to the forces, the shearing forces are resolved into (t) tangential or shearing stresses, and (n) normal (tensile or comp) stresses.

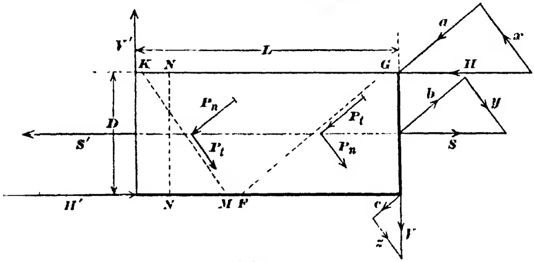

Fig. 17.

106. Thus, Fig 17, let a bar, of length, L, and depth, D, be subjected to a tension, $S = S'$, in line with its hor axis, and to two pairs of forces, $V = V'$ and $H = H'$, as shown; V and V' constituting a right-hand vert shear, while H and H' constitute a left-hand hor shear.

Suppose the bar divided by a section, as $N\ N$, $F\ G$ or $K\ M$, and consider the forces acting, in either case, upon the right-hand segment of the bar as thus divided.

Upon the *normal* section, $N\ N$, the tension, S, and the hor shear, H, act normally (S as tension, H as compression), and the vert shear, V, tangentially (as shear), but, for an *oblique* section, $F\ G$ or $K\ M$, we first resolve each force, S, V and H, into two components, b and y, c and z, a and x, respectively normal and parallel to the section, as shown by the force-triangles on the right.* Then, summing these comps, algebraically, we obtain the resultant forces, P_n (normal) and P_t (tangential or shearing), acting upon the section in question. With the forces, S, V and H, as shown in Fig 17, we have.

On sec $F\ G$, P_n, tension, $= y + z - x$;

P_t, right-hand shear, $= a + c - b$;

On sec $K\ M$, P_n, compression, $= a + c - b$;

P_t, right-hand shear, $= y + z - x$.

107. If, now, we examine **all possible planes** cutting the body at a given point, we shall find (1) one such plane upon which the resultant unit *tensile* stress reaches its max; (2) another, normal to (1), upon which the resultant unit *comp* stress reaches its max; and (3) two planes, normal to each other & bisecting the right angles betw planes (1) & (2). Upon the two planes last named, (3), the resultant unit *shearing* stresses reach their max.

---

*In order that, for either force, S, V or H, the two force-triangles (for the two sections, $F\ G$ and $K\ M$) may be identical, and thus simplify the figure, we take the two sections, $F\ G$ and $K\ M$, normal to each other.

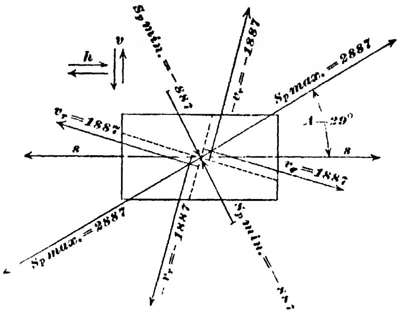

Fig. 18.

108. Let Fig. 18 represent **a small element** in a bar under tensile & shearing stresses; and let it be required to determine the **positions of these planes and the corresponding max stresses.** Let

s = the original normal (tensile or comp) unit stress;
v = " " vertical (shearing) unit stress;
= h = " " horizontal (shearing) unit stress;
s_p = " max or min resultant normal unit stress;
v_r = " max resultant shearing unit stress,
A = " angle betw s and s_p.

Then $\tan 2A = \dfrac{v}{s/2}$ . . . . (1)

$v_r = \sqrt{(s/2)^2 + v^2}$ . . . . (2)

$s_p \max = s/2 + v_r = s/2 + \sqrt{(s/2)^2 + v^2}$ . . . . . (3)

$s_p \min = s/2 - v_r = s/2 - \sqrt{(s/2)^2 + v^2}$ . . . . . (4)

If s is tension { + sign gives max tension; − " " " comp = min tension }
If s is comp { + " " " comp; − " " " tension = min comp. }

109. Example. Let

s = 2000 lbs/sq inch, tension (not drawn to scale);
v = h = 1600 " / " " , shear (" " " ").

Here v is left-handed, h right-handed. If this be reversed, the angle, A, betw the resulting tension, s_p, & the hor, will be *below* the neut axis.

110. Then $\tan 2A = \dfrac{v}{s/2} = \dfrac{1600}{1000} = 1.6$; $2A = 58°$; $A = 29°$;

$v_r = \sqrt{(s/2)^2 + v^2} = \sqrt{1000^2 + 1600^2} = 1887$;
$s_p \max = s/2 + v_r = 1000 + 1887 = 2887$ (tension)
$s_p \min = s/2 - v_r = 1000 - 1887 = -887$ (comp)

111. In other words, **we have, as resultants,** (1) a max unit tension, s_p max = 2887 lbs/sq in, forming an angle, A = 29°, with the axis of the bar or with the direction of s; (2) a min unit tension or max comp, s_p min = − 887 lbs/sq in, normal to s_p max; (3) a right-hand unit shear, v_r = 1887 lbs/sq in; and a left-hand unit shear, − v_r = − 1887 lbs/sq inch; the

directions of the shearing stresses bisecting the right angles betw the max normal stresses.

112. The max tension and compression, at any point, are called the "**principal stresses**" for that point.

Horizontal and Vertical Shear in Beams.

See also pp 440 &c, 446 &c, 450 to 453, 478-9.

113. Let Fig. 19 represent the left half of a **homogeneous beam**, of rectangular section; breadth, b, = 1 inch; depth, d, = 10 ins; span, L, = 100 ins; with cen load, W,* of 200 lbs; left reaction, $R = W/2 = 100$ lbs. Weight of beam neglected. The bendg mom, at cen of span, is $M = RL/2 = WL/4$* = 5000 inch-lbs; and the mom decreases uniformly,* from its max, at cen of span, to zero at the supports. In the extreme upper & lower fibers, the longitudinal unit stress, (¶ 10, p 468) s, = MT/I, where $T = d/2$ = dist from neut axis to extreme fibers = 5 ins; I = inertia mom of cross section = $bd^3/12$ = 1000/12. Hence, in Fig 19, $s = 12 \times 5\ M/1000 = 0.06\ M$. Now s, being thus proportional to M, also decreases uniformly,* from its max, at cen of span, to zero at the supports. Values of M and of s, for the sections 0, a, b, c, d, e, are figured on the diagram.

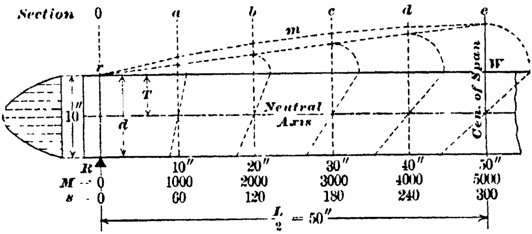

Fig. 19.

* Under a *uniformly distributed* load, the bendg mom, at cen of span, is $WL/8$; and the bendg moms, M, and the resulting longitudinal unit stresses, s, vary as the ordinates of a parabola, as indicated by the dotted parabola, $r\ m\ e$, at top of Fig 19, which corresponds to a uniform load = 400 lbs = 2 W The unit shears, v, in a given hor section, then decrease uniformly, from a max, at the supports, to zero at the cen of the span. Compare 3d and 4th figures, p 474.

114. The unit hor **tensile and comp stresses,** *s*, at the several points in any vert section, are **proportional to the dists** of those points **from the neutral axis,** as indicated by the diagram at each vert section, Fig 19.

115. In Fig 20, let *n* and *g* be two vert sections of this beam, such that, at *n* and at *g*, the extreme unit fiber stresses are: $m\ n = 15$, and $u\ g = 25$, respectively. Then the **rectangular portion, n f, of the beam, betw sections n & g,** is acted upon by a series of net or resultant forces, ranging from compression, $e\ g = u\ g - m\ n = -25 - (-15) = -10$, at the top, to tension, $= +10$, at bottom, as indicated by the diagram, *e k*.

116. Suppose the piece *n f* to be divided into 10 hor strips of equal depth, = 1 inch. Then the **net unit stresses,** *s*, acting at the tops and bottoms of these strips, respectively, are those, (—10, —8, —6, ... 6, 8, 10) figured from *e* to *k*; and the mean stress, or (since depth of each strip = *b* = 1) **the force, acting upon each strip,** is that (—9, —7, —5, ... 5, 7, 9) figured betw *g* and *f*.

117. These forces are transmitted, from strip to strip, thru their surfs of contact; and, in determining the shearing force, acting in the hor plane betw any 2 strips, we regard the upper (or lower) strip as acted upon by its own push or pull plus (algebraically) those of all the strips above (or below) it.

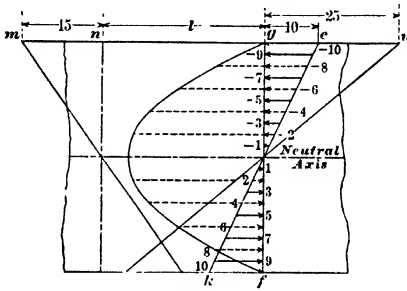

Fig. 20.

118. Thus, the 3d strip from the top is pushed to the left by a force of $-9 -7 -5 = -21$, while the 4th strip, just below it, is pulled to the right by a force of $9 + 7 + 5 + 3 + 1 - 1 - 3 = 21$. Hence the surf betw the 3d and 4th strips, sustains a counterclockwise **shear** of 21; which, divided by the area, $b\,l = l$, of that surface, gives the **unit shear** in the plane betw the 3d and 4th strips. With central load,* this unit shear is uniform from each support to cen of span, where it changes sense (from plus to minus, or vice versa) but is of the same intensity in the other half-span. See 3d Fig, p 474.

119. In any vert section of the beam, let

V = the total shear
= " reaction of either support, minus the sum of all loads betw that support and the section;
I = " inertia moment with respect to the neut axis;
b = " breadth; d = depth;
a = " area above (or below) any given point in the section;
c = " dist from neut axis to grav cen of a;
$M_s = a\,c$ = static mom of a, with respect to the neut axis;
v = the unit vert shear = unit hor shear at a given point.

120. Then

$$v = V \frac{M_s}{I} \div b = V \frac{a\,c}{I\,b}$$

* See foot-note p 494 *c*.

At the neut axis, M_s (= $a\,c$) = $\frac{d\,b}{2} \cdot \frac{d}{4} = \frac{d^2\,b}{8}$.

Hence, **at the neutral axis:**

$$v = V \frac{d^2}{8\,I} = V \frac{12\,d^2}{8\,b\,d^3} = \frac{3}{2} \cdot \frac{V}{b\,d}$$

$$= \frac{3}{2} \times \text{the mean vert shear in the cross section.}$$

See also ¶¶ 51 etc.

Since, under a center load, (¶ 113 and Fig 19) s increases *uniformly*, from zero (at support) to s_{max} (at span center), we have, for the increase of s, in any portion, as $n\,g = l$, Fig 20, of the span:

$$s_g - s_n = s_{max} \frac{l}{L/2} = 2\,s_{max} \frac{l}{L}.$$

121. At the left of Fig. 19 is a **diagram showing the unit shears** in the several hor sections.

122. Let Fig 21 represent a small element of a body, of unit thickness, normal to the paper, and acted upon by a right-hand vert shear, $V = v\,D$, (where v = the unit vert shear, and D = the depth of the element) and by a left-hand hor shear, $H = h\,L$ (where h = the unit hor shear, and L = the length of the element). For equilib of moments, we must have

$$V\,L = H\,D; \quad \text{or } v\,D\,L = h\,L\,D; \quad \text{or } v = h.$$

In other words,

unit vert shear = unit hor shear.

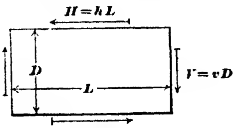

Fig. 21.

Maximum Unit Stresses in Beams.

123. The common theory of beams (pp 466 to 494, ¶ ¶ 1–103) considers only the **longitudinal tensile and compressive forces** and the vert and hor **shearing forces**, due directly to the load and to the upward reactions of the supports, and acting, at any point, upon *vert and hor planes* passing thru such point; but, except in certain limited portions of the beam, these stresses are **not the maximum stresses** acting at such point; for they combine to form resultant *diagonal* stresses, acting upon *diagonal* planes (passing thru the same point); and, upon some of these diag planes, the resulting normal and tangential stresses are greater than either of the original stresses.

124. The common theory is sufficiently well **adapted** to beams of many kinds, and especially to **steel beams**, where the longitudinal forces are resisted by the flanges, and the shears by the web; but in certain portions of deep and heavily loaded beams, especially those of **reinforced concrete**, the diagonal resultant or **maximum stresses** are the *ruling* stresses, and must not be neglected.

125. In a beam, at top and bottom, we have, respectively, hor tensile and comp stresses only, and, at the neut axis, shear (vert & hor) only; but, at all other points, we have **shear** (vert & hor) **acting conjointly with hor stresses**, either tensile or comp. At all points, these shearing and longitudinal stresses may be **resolved into components**, normal & tangl to any plane, at pleasure, as in the case of the bar or bolt, Fig 17.

126. Thus, each element of the beam, Figs 22, 23, 24, is acted upon by hor & vert forces (unit stresses), which, acting upon diagonal planes, are resolved into diagonal components, and these components may be alge-

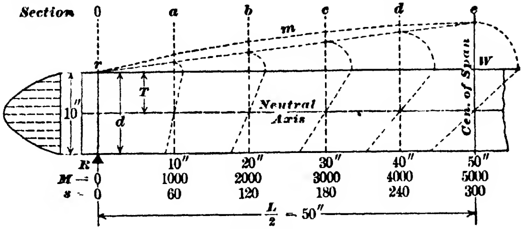

Fig. 22.

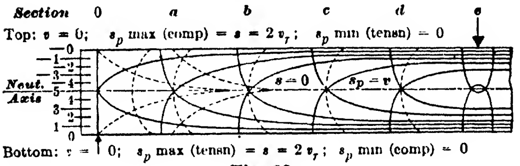

Fig. 23

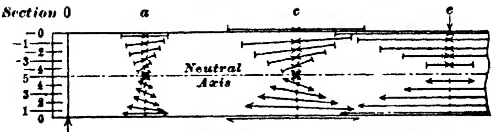

Fig. 24.

braically **summed into resultants;** but the original stresses vary in intensity, and the resultant stresses both in intensity and in direction, from point to point. For the **directions and values** of these resultant stresses at their maxima, we have, from Eqs 1-4, ¶ 108, p 494*b*:

$$\text{Tan } 2\,A = \frac{v}{s/2} \quad\ldots\ldots(1)$$

$$v_r = \sqrt{(s/2)^2 + v^2} \quad\ldots\ldots(2)$$

$$s_p = s/2 \pm v_r = s/2 \pm \sqrt{(s/2)^2 + v^2} \quad\ldots\ldots(3)(4)$$

where

s = original unit tensile or comp stress at the point;
v = original (vert or hor) unit shear at the point.

The max normal stresses, s_p, are called the **principal stresses.**

127. Applying these formulas at numerous points in the profile of the beam, Fig 22, we are enabled to construct **curves,** Fig 23, showing the **directions** of the stresses; and to plot, as in Fig 24, for given points, the **directions and intensities** of the stresses there acting. At any given point, Fig 24, we have resultant normal and shearing stresses analogous to those in Fig 18, p 494 *b*; but, in the present Fig 24, owing to want of space, only the *max principal* stress, s_p *max*, is shown for each point selected.

128. In Fig. 23, the directions of the **principal stresses**, s_p, are represented by the solid curves; those of the **resultant shears**, v_r, by dotted curves.

Of the solid curves (principal stresses)	concave	horizontal at cen of span	at 45° with	at 90° with
The tension curves are	upward	below neut axis	neut axis	top of beam
The compression curves are	downwd	above " "	" "	bot " "

The tensile and comp curves are normal to each other at their intersections.

129. Following any curve (concave upward) of normal tension,* we find that,

(1) for its point of **tangency with the hor** (viz: at cen of span) s_p max = tension = s, s_p min = comp = 0;

(2) for the point **where the curve crosses the neut axis** (at 45°) s_p max (tension) = s_p min (comp) = v_r = $\pm v$ (shear),

(3) **above the neut axis**, the tension becomes s_p min, and continues diminishing, as the direction approaches the vert, becoming zero at top, where A = 90°. Above the neut axis, for points in the same curve, the *compression* (*normal* to the curve) is now s_p max, and increases from s_p = v_r = $\pm v$, at the neut axis, to s_p max (comp) = s, at top.

130. Where v = zero (viz. at any point in the vert cross section at cen of span, and along the extreme upper and lower fibers), we have (¶ 126):

$$v_r = s/2$$
$$s_p \max = s/2 + v_r = s; \qquad \tan 2A = 0;$$
$$s_p \min = s/2 - v_r = 0; \qquad \tan 2A = 0.$$

131. The equation, $\tan 2A = 0$, gives either $2A = 0°$ or $2A = 180°$; *i. e.*, $A = 0°$, or $A = 90°$; but we know that, at cen of span and along the extreme upper and lower fibers, s_p max is hor, or $A = 0°$; and s_p min is vert, or $A = 90°$.

132. Where s = zero (as at the neut surf and where bending mom = zero), we have (¶ 126): $v_r = \pm v$; $s_p \max = s_p \min = \sqrt{v^2} = \pm v$; $\tan 2A = \infty$; $2A = 90°$; and $A = 45°$.

133. Of the (dotted) **shear curves**, Fig 23, those of one set are tangential to the neut axis and reach top & bottom of beam at angles of 45°, tending away from cen of span; while those of the other set are normal to these and to the neut axis at their intersections, reaching top and bottom of beam at 45°, tending toward cen of span.

MOMENTS IN CONTINUOUS BEAMS.

See also ¶¶ 78, etc.

134. Figs 25 and 26 show positive and negative **bending moments in two continuous beams**, Fig 25 of two equal spans, and Fig 26 of three equal spans, resting freely upon their supports. Each span = 1. Fig 26 (three spans) may be used, with sufficient approximation, for cases where the spans are more numerous.

* *Conversely* for curves (concave downward) of normal *compression*.

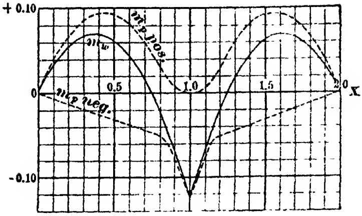

Fig. 25.

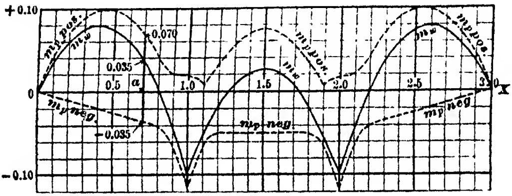

Fig. 26.

135. At any cross section, the ordinate, betw the axis, 0 X, of abscissas, and the curve, (1) m_w, (2) m_p *pos*, or (3) m_p *neg*, represents, respectively, by the scale of ordinates on the left, (1) the dead load moment, m_w, (2) the max positive live-load mom, m_p *pos*, or (3) the max negative live-load mom, m_p *neg*, at that section, the dead load (1 per unit of span) being uniformly distributed over the entire length (two or three spans, as shown) of the beam, and the live load (1 per unit of span) being uniformly distributed alternately over two portions of the length of the beam, said portions being, for each cross section, such that the uniformly distributed live load, placed upon said portions, will produce, alternately, the max pos and the max neg mom at that section.

136. In an actual beam, at any point, we have, for bending mom:

$$M = m_w \, w \, L^2 + m_p \, p \, L^2 ;$$

where

m_w = the ordinate, at the point, from 0 X to the curve m_w;
m_p = " " " " " " " " " " " " m_p *pos* or m_p *neg*;
w = uniform dead load per unit of span;
p = " live " " " " " " , placed as explained in ¶ 135.
L = the actual span.

Thus, at the point, a, Fig 26 (distant 0.7 L from 0), we have, by scale, m_w = 0.035; m_p *pos* = 0.070; m_p *neg* = − 0.035. Hence, at point a,

$$\text{max pos mom} = 0.035 \, w \, L^2 + 0.070 \, p \, L^2;$$
$$\text{max neg mom} = 0.035 \, w \, L^2 - 0.035 \, p \, L^2.$$

If, therefore, $p = w$, the max neg mom, at a, is zero, and there is no resultant neg mom to the left of a; but, if $p = 2\,w$, we have $w = p/2 = (w + p)/3$; and, at a, with $p = 2\,w$:

$$\begin{aligned} \text{max neg mom} &= 0.035 \, w \, L^2 - 0.035 \times 2 \, w \, L^2 \\ &= 0.035 \, w \, L^2 - 0.070 \, w \, L^2 = - 0.035 \, w \, L^2 \\ &= - 0.035 \, (w + p) \, L^2/3. \end{aligned}$$

COLUMNS IN GENERAL.

Strength of Columns, Pillars, Struts, of Uniform Cross Section.

(For iron and steel columns, see pp 1189, etc. For wooden columns, see pp 1143, etc.)

1. The axis of a column is a line passing through the centers of gravity of all its cross sections.

2. If the line of action of the load coincides with the axis of the column in the end sections, the column is said to be **axially loaded**: otherwise, **eccentrically loaded.**

3. Under an axial load, if the axis remains mathematically straight, it coincides with the line of pressure throughout the length of the column, and the stress is uniformly distributed over each cross section, as indicated by the parallelogram, *a b*, Fig 2, but eccentricity of loading, Fig 1 *a*, or lack of straightness in the axis, Fig 1 *b*, or of homogeneity in the material, will cause the axis to diverge from the line of pressure.

4. When the axis and the line of pressure fail to coincide, in any section, their divergence sets up, in that section, a "couple" (see ¶¶ 148, etc, pp 401, etc; ¶¶ 155, etc, pp 404, etc) represented by the two triangles, *b c d* and *e c f*, Fig 2, ¶ 6, below.

5. In all cases, therefore, **the diagram** of the stresses in the cross section consists of the **parallelogram**, *a b*, modified or not (as the case may be) by the **two triangles**, *b c d* and *e c f*. (In Fig 2, the extreme fiber stresses are: $s = af\ (= ae + ef)$ and $gd\ (= gb - bd.)$

6. In very short columns, axially loaded, the parallelogram is but little (if at all) affected by the triangles; i e, the pressure is nearly or quite uniformly distributed over the cross section; while, **in very slender columns**, on the contrary, the pressure is practically certain to be unequally distributed; and the disturbing effects, represented by the two triangles, may become the principal feature; so that the maximum unit stress, on the concave side, may greatly exceed the mean stress, *a e* or *g b*, Fig 2; while the unit stress, *g d*, on the convex side, may fall to zero or may even become tension.

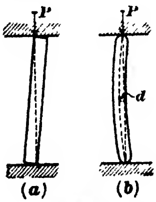

Fig. 1.

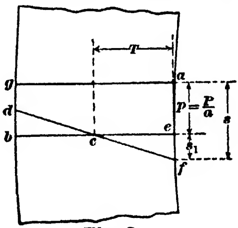

Fig. 2.

7. In very slender columns, under moderate deflections, the changes of length in, and therefore the stresses exerted by, the extreme fibers, are relatively small. Hence, the column may fail to support its load long before these stresses reach the ultimate strength, or even the elastic limit, of the material; as when a whale-bone is compressed endwise between thumb and finger, and thus sprung out laterally.

8. But, as the deflection, *d*, Fig 1 *b*, increases, the moment, *Pd*, of the load, *P*, increases also. The changes of length of the fibers, and therefore the stresses exerted by them, increase also, owing to the increase of curvature; so that, eventually, further movement of the load may be prevented, or, if the load is sufficient, the column may be broken or permanently crippled by it.

9. A very slight obliquity, Fig 1 *a*, or deflection, Fig 1 *b*, may reduce the strength as much as 50 per cent; and differences of 10 per cent or more, in the ultimate load, may occur between two pillars which, to all appearances,

are precisely similar, and tested under the same conditions. Hence, the behavior of columns is much less certain than that of pieces in tension, or even of beams; and **liberal safety factors should be employed** in using formulas or tables for columns.

10. This lack of certainty, in respect to the strengths of columns, is especially unfortunate in view of the necessary and extensive use of **columns as compression members in bridge and roof trusses.** See Quebec Bridge, p 1202 [under Iron & Steel Columns].

11. The neutral axis of any section is a line, in that section, passing through its center of gravity and perpendicular to the plane in which deflection takes place, or in which it is supposed to take place. A cross section may therefore have a number of neut axes, as the col may be supposed to deflect in any one of a number of planes. Usually, however, when a col, of homogeneous material, is left free to deflect in any plane, the plane of deflection is determined by the shape of its cross section, and is that of its least radius of gyration. Thus, if the section is circular, whether solid or hollow, deflection may equally well occur in any plane; but, in a square, deflection occurs in a plane parallel to either side; in a rectangle, in a plane parallel to the shorter sides, etc, etc.

12. When the plane of deflection is predetermined by some constraining feature, as by the pins in Figs 3 *c*, **economy of material** requires that the section be so disposed, with reference to the pin, etc, that the **least radius of gyration** (see pp 353 *a*, *b*) shall be perpendicular to the plane of deflection, as so predetermined. When the plane of deflection is not thus predetermined, economy of material requires that the section be so designed that the several radii of gyration be as nearly equal as may be.

13. Since a structure is in danger when any portion of it sustains a stress exceeding the **elastic limit,** that limit should be taken as constituting the ultimate stress.

14. Fatigue. In our following remarks on this subject, the pillars are supposed to sustain a *constant* load; and the ultimate or breaking load referred to is that one which would, during its first application, cripple or rupture the pillar in a short time. But struts in bridges etc often have to endure stresses which vary greatly in amount from time to time. Their ultimate load is then less. See p 465.

15. The resistance of a column is greatly affected by the arrangement of its ends, see Fig 3, below. Thus:

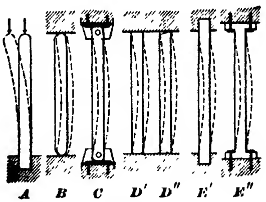

Fig. 3.

A. Free end. Column free to deflect, in any direction, about the other (fixed) end.

In the following cases, the ends are supposed to remain stationary, altho the axis is more or less free to bend.

B. Round ends. Axis free to deflect in any vertical plane.

C. Hinged or pinned ends. Deflection limited to one vertical plane.

D. Flat or square ends. Tangents to axis of column, at ends, fixed in position (see *D′*), until rotation, at ends, takes place, as in *D″*.

E. Fixed ends. Tangents to axis of column, at ends, fixed in position.

The two ends of a column may be differently arranged. Thus, one may be fixed and the other round; or one flat and the other pinned, etc.

Axial Loading.

16. The weight of the column itself, whether vertical or horizontal, is here neglected.

17. Let all dimensions be expressed in one and the same unit, as the inch, and all forces in one and the same unit, as the pound; and let

a = area of cross section;
r = its least radius of gyration;
I = ar^2 = its least moment of inertia;
T = distance from neutral axis of section to extreme fiber on concave side of bent col.
L = unsupported length of col (see ¶ 41).
K = $\frac{L}{r}$ = length ratio, or slenderness, of col;
b, m, c = coefficients, as explained below.
P* = load on column;
p* = P/a = av unit load on col;
s* = max unit stress in cross section,
s_e = elastic limit of material;
s_s = max unit stress in short col.;
E = elastic modulus of material;
e = eccentricity of load, P; Fig 5.
d = deflection under load P Fig 1 b = max dist from line of pres to axis of col.

18. Euler's formula. See Fig 4. Let the column be slightly bent by a lateral force. Then the average unit load p, which will just suffice to hold the column in equilibrium, in its bent condition, is

$$p = \frac{P}{a} = b \cdot \frac{\pi^2 E}{K^2}; \qquad K = \pi \sqrt{\frac{bE}{p}} \quad \ldots\ldots\ldots (1)$$

For round ends, b = 1; for fixed ends, b = 4. For one round and one fixed end, b is usually taken between 2 and $2\frac{1}{4}$.

Under any less load, or less K, the column will return to the straight condition. Under any greater load, or greater K, the bending will increase. See ¶ 8.

19. For very long columns, **Euler's formula**, ¶ 18, gives results agreeing well with experiment; but, for practical lengths, it gives excessive loads. See lines $E\,e$, $E'\,e'$, Fig 4. For practical lengths (if the column could remain straight and axially loaded), and down to short blocks, we should have, for the ultimate strength, $p = P/a = s_e$ = elastic limit, and the diagram would be $J\,b\,e$ or $J\,b'\,e'$, Fig 4. See ¶ 13.

20. But, owing to unavoidable imperfections, columns of usual lengths are liable to lateral deflection, and the diagram therefore falls below the line $J\,b\,b'$. See "Parabolic Formula," ¶ 28.

21. Rankine's formula† for axially loaded columns of practical lengths. Fig 2.

As in ¶ 17, let

p = mean unit load on column; **s** = max unit stress in cross sectn;
K = L/r = unsupported length ÷ least rad of gyration; **m** = a coefficient.

22. In an *axially* loaded column, (¶ 2) while unbent, we have

$$s = p = P/a.$$

23. But, when the column *bends*, an *additional* unit stress, s_1, is thereby thrown upon the material on its concave side (see ¶ 6), and we have, for the total unit fiber stress, s, on that side:

$$s = p + s_1 = (P/a) + s_1$$

24. The bending moment, due to the deflection, d, Fig 1 b, of the column, is $M = Pd$.

---

* Under any given conditions, P and p are the total load and the avge unit load, respectively, corresponding to the extreme fiber stress, s, existing under those same conditions. Thus, P, p and s may be those corresponding to ultimate or safe or any other loading.

† W. J. M. Rankine, "Civil Engineering," p 523. "Gordon's formula," attributed to Prof Lewis Gordon, of Glasgow, uses the least *diameter*, instead of the least *radius of gyration*, of the cross section.

25. As in beams, p 467, we have, for equilibrium between the bending moment, M, and the resisting moment, R,

$$M = R; \quad \text{or } Pd = \frac{s_1}{T} I.$$

$$\text{Hence } s_1 = \frac{M\,T}{I} = \frac{P\,d\,T}{a\,r^2} = p\,\frac{d\,T}{r^2}$$

$$\text{and } s = p + s_1 = p + p\,\frac{d\,T}{r^2} = p\left(1 + \frac{d\,T}{r^2}\right)$$

26. In a beam, p 481, for a given fiber stress, the deflection, d, is proportional to L^2/T. Assuming that this is true of columns also, we have:

$$d = m\,(L^2/T)$$

Hence,

$$s_1 = p \,.\, \frac{d\,T}{r^2} = p \,.\, m\,\frac{L^2}{T} \,.\, \frac{T}{r^2} = p\,m\,K^2; \quad \text{and}$$

$$s = p\,(1 + m\,K^2) \quad \ldots\ldots (2)$$

Hence, **Rankine's formula:**

$$p = \frac{P}{a} = \frac{s}{1 + m\,K^2} = s\,\frac{1}{1 + m\,K^2} \quad \ldots\ldots (3)$$

$$K = \sqrt{\frac{\frac{s}{p} - 1}{m}} \quad \ldots\ldots (3a)$$

27. Ritter* gives $m = s_e/(b\,\pi^2\,E)$; and Crehore† gives $m = s/(b\,\pi^2\,E)$. For values of b, corresponding to different arrangements of the ends of the column, see ¶ 18.

For values of s and of $1/m$, commonly used in practice, and for diagrams of values of $p/s = 1/(1 + m\,K^2)$, in columns of metal and wood, see Iron and Steel Columns, pp 1189, etc, and Wooden Columns, pp 1143, etc.

28. Parabolic formula. J. B. Johnson.‡

s_e = elastic limit of the material; $\quad$ q = a coefficient.

$$\left.\begin{array}{l}\text{Ultimate strength}\\ \text{lbs per sq inch,}\end{array}\right\} = p = \frac{P}{a} = s_e - \frac{s_e^2}{q\,\pi^2\,E}\,K^2 = s_e - c_p\,K^2 \ldots (4)$$

$$K = \sqrt{\frac{(s_e - p)\,\pi^2\,E\,q}{s_e^2}} \quad \ldots\ldots (4a)$$

For values of q, see Iron and Steel Columns, ¶ 20, p 1197. See also Wooden Columns, ¶ 6, p 1146.

29. Straight-line formula. For the sake of simplicity, with columns of practical lengths, we may use the straight-line formula:

$$\text{Ultimate strength, lbs per sq inch} = p = P/a = s_s - c\,K \quad \ldots\ldots (5)$$

$$K = (s_s - p)/c. \quad \ldots\ldots (5a)$$

For values of s_s and c, assigned by Thos. H. Johnson and others, see Steel and Iron Columns, pp 1189, etc, and Wooden Columns, pp 1143, etc.

The error, involved in the use of this formula, is probably much less than those inseparable from the nature of columns.

30. Fig 4 shows a **comparison of results by formulas for, and experiments upon, round-end mild steel columns**, as follows:—**For Euler's formula**, p is that unit load, in lbs per sq inch, which will just hold, in slightly bent condition, a column of the given E and K. **For the other formulas** and for Tetmajer's experiments, p is the unit *crippling* load, in lbs per sq inch.

* Mitteilungen der Materialprufungsanstalt am schweizerischen Polytechnikum in Zürich. Heft VIII, 1896.

† $1.489 = s_c^2/\pi^2 b E = 42,000^2/(9.87 \times 30,000,000\ b)$. For round ends, $b = 4$. Materials of Construction, p 363. Compare Iron and Steel Columns, ¶ 20, p 1197.

31. T. H. Johnson finds that, **for all tangents to Euler's curve,** the co-ordinates of the point (as h, Fig 4) of tangency, are:

Abscissa, $x = K_h = \sqrt{3\,z\,E/s_s}$; Ordinate, $y = p_h = s_s/3$;

where $z = \pi^2 = 9.87$, for round ends; $z = (5/3)\,\pi^2 = 16.45$, for hinged ends, and $z = (5/2)\,\pi^2 = 24.67$, for flat ends; and s_s = the ordinate of that point, H, where the tangent meets the axis of ordinates.

Mr. Johnson takes $E = 27{,}000{,}000$ lbs per sq in, and $s_s = 52{,}500$. Hence, in Fig 4, $x = 123.3$, and $y = 17{,}500$.

32. Tetmajer gives the following values, x', for the abscissa of the point where his straight line meets Euler's curve

	E	x'
Wood	1,400,000	100
Cast iron	14,000,000	80
Wrought iron	28,000,000	112
Structural steel, soft	30,000,000	105
Structural steel, medium	32,000,000	105

Hence, in Fig 4, his straight line, $T'\ t$, meets Euler's curve, $E'\ e'$ (not tangentially) at t, where $K = 105$.

33. J. B. Johnson takes $E = 30{,}000{,}000$ lbs per sq in; and his curve, $J\ j$, is tangent to Euler's curve, $E'\ e'$, at the point where $K = 120$. For mild steel columns, with pin ends, he limits K to a max value of 150

34. Stepped formula. J. R. Worcester. In view of the wide divergence in the strengths of columns, as found by the several formulas and coefficients in use, and of the similarly wide variation in the results of experiments, Mr. J. R. Worcester * considers it idle to assume a different value of p for each value of K; and proposes a *fixed* value of p for a certain *range* of values of K. Thus, for compression members of structural steel in bridges he proposes ($K/12 = L$, in *feet*, ÷ r, in *inches*)

for $K/12$ from 2 to 4, $p = 13{,}000$ lbs per sq inch,
for $K/12$ from 4 to 6, $p = 12{,}000$ lbs per sq inch;

and so on, with a decrease, in p, of 1000 lbs per square inch for each succeeding increase of 2 in the value of $K/12$. For steel columns, he gives $(K/12) \not> 16$. Mr. Worcester's formula gives a "stepped" diagram, composed of horizontal and vertical lines.

* Trans Am Soc Civ Engrs, Vol 54 p 417, June, 1905.

Eccentric Loading. Fig 5.

35. Hitherto we have assumed that the column is axially loaded (see ¶ 2) and, in considering inequality of distribution of stress in a cross section, Fig 2, with its resulting excess load on the extreme fibers of the concave side, we have taken into account only that excess, s_1, which is due to the *deflection* of an *axially* loaded column.

36. But it very commonly happens that columns are (accidentally or intentionally) eccentrically loaded; and this eccentricity, e, brings, upon the extreme fibers on the side nearest the line of pressure, an *additional* excess unit stress, s_2, Fig 5. If the column remained perfectly straight, we should have (see pp 467–8) $s_2 = TM/I = TPe/ar^2 = (P/a)(Te/r^2) = pTe/r^2$; and hence, in a bent column, (see Eq 2, where $s_1 = p\,m\,K^2$),

$$s = p + s_1 + s_2 = p\left(1 + mK^2 + \frac{Te}{r^2}\right) \qquad (6)$$

and

$$p = \frac{P}{a} = \frac{s}{1 + mK^2 + \dfrac{Te}{r^2}} \qquad (7)$$

$$K = \sqrt{\frac{\dfrac{s}{p} - 1 - \dfrac{Te}{r^2}}{m}} \qquad (7a)$$

where, as in ¶ 17:

- **p** = mean unit load on column; **e** = eccentricity, Fig 5;
- **s** = maximum unit stress in cross section;
- **K** = L/r = unsupported length ÷ least radius of gyration;
- **T** = dist from neut ax of sectn to extreme fiber on concave side.

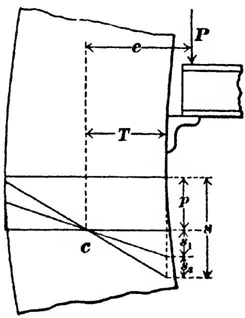

Fig. 5.

37. As a matter of fact, the deflection of the column, provided for in the term, mK^2 (Eqs 6 and 7), slightly increases the eccentricity, e, of the load, (see Fig 5) and this is neglected in the term Te/r^2. Hence, the fiber stress, s, given by equation (6) is a little too small, and the load, p, given by equation (7), is a little too great; but the discrepancy is ordinarily regarded as negligible in practice.

38. For round end columns, **J. M. Moncrieff*** gives:

$$p = \frac{P}{a} = \frac{s}{1 + \frac{Te}{r^2}\left(\frac{48\,E + p\,K^2}{48\,E - 5\,p\,K^2}\right)} \quad\ldots\ldots\ldots\ldots(8)$$

$$K = \sqrt{\frac{48\,E}{5\,s + p\,(Te/r^2 - 5)}\left(\frac{s}{p} - 1 - \frac{T\,e}{r^2}\right)} \quad\ldots\ldots\ldots\ldots(8a)$$

39. Let

M = $P\,e$, Fig 5, = moment of an eccentric load, P, about c;
I = moment of inertia of cross section;
T = distance from neutral axis to furthest fiber;
X = I/T = section modulus of cross section in direction of bending;
s_2 = maximum fiber stress due to eccentricity only.

Then

$$s_2 = M\,T/I = M/X \quad\ldots\ldots\ldots\ldots(9)$$

40. With columns supposed to be axially loaded, the loading is, in fact, very generally more or less eccentric, and to an unknown degree; but where a load is applied at a point at or beyond the edge of the column, as in Fig 5, the eccentricity is so great that unavoidable uncertainties, as to its exact amount, become relatively negligible, and Eqs (7) and (7*a*) may be used with some confidence.

41. If a very long col be so **braced at intervals** as to prevent its bending at those points, then its length becomes virtually diminished, and its strength increased. Thus, if a column 100 ft long be sufficiently braced at intervals of 20 ft, then the load sustained may be that due to a column only 20 ft long.

Cautions.

42. Cast iron columns are subject to blow holes and to other hidden defects, and are easily broken by side blows. Columns of all kinds are subject to jars and vibrations from moving loads. It very rarely happens that the pressure is equally distributed over the whole area of the pillar; or that the top and bottom ends have perfect bearing at every part.

43. In column tests, exceptionally high results may occur where the conditions happen to approach the ideal.

---

* Trans Am Soc Civ Engrs, Vol 45, p 349, June, 1901.

SHEARING STRENGTH.

Shearing or detrusion occurs when a body is acted upon by two opposite forces in parallel and closely adjacent planes, tending to slide some of the particles over the others. In Fig 1, the two forces are (1) the downward pressure of the weight, W, and (2) the upward reaction of the support, A.

In **single shear**, Fig 1, the shearing area, a, = the section $g\,g$. In **double shear**, Fig 2, $a = g\,g + o\,o = 2 \times g\,g$. In Fig 3, $a = 6 \times$ cross section of piece. In Fig 4 (single shear), a = section $c\,c$. In punching rivet holes, a = circumference of hole $\times$ thickness of plate

In any case, if S = the ultimate unit shearing stress, Shearing strength = S a.

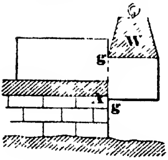

Fig. 1

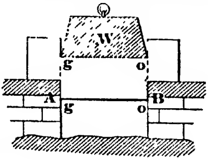

Fig. 2

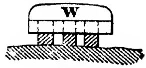

Fig. 3

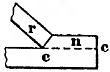

Fig. 4

Ultimate unit shearing stress, S, in lbs per sq inch. The following figures indicate the range of values of S in metals and in timber.

Metals. Wrought iron, 35,000 to 55,000; cast iron, 20,000 to 30,000; steel, 45,000 to 75,000; copper, 33,000.

		With the grain, Fig 4.	Across the grain.
Timber: From our experiments:	Spruce	250 to 500	3,250
	White pine	"	2,500
	Hemlock	"	"
	Yellow pine	......	4,300 to 5,600
	Oak	400 to 700	....
	White oak	......	4,400

TORSIONAL STRENGTH.

Torsion occurs when a body is acted upon by two couples or moments of contrary sense and in different planes. Thus, torsion takes place in a brake axle when we try to turn it while its lower end is held fast by the brake chain; and in shafting, when it transmits the motive power of an engine to tools. Suppose such a body to be divided, by cross sections, into layers. Then each layer tends to shear across from those next to it. Hence, in order to maintain equilibrium, each two adjacent layers must exert, in the cross section between them, an internal resisting moment equal to one of the two external and contrary torsional moments.

Resisting moment in a circular cross section of a cylindrical shaft. Let

P = the torsional force of one of the two external moments..... ....in pounds;
l = its leverage, = its distance from the axis of the shaft..................in inches;
M = P l = external or torsional moment..................................in inch-pounds;
T = distance from axis to farthest fibers, = radius of shaft.................in inches;
D = diameter of shaft, = 2 T...in inches;
S = unit shearing stress in farthest fibers.......................in pounds per sq inch;
t = distance from axis to any given fiber...in inches
s = unit stress in said given fiber ....in pounds per square inch;
a = area of said given fiber..in square inches;
F = total stress in said fiber ....in pounds;
r = resisting moment of said fiber about the axis.....................in inch-pounds;
R = internal resisting moment of the entire cross section
= Σr = sum of resisting moments of all the fibers..................in inch-pounds;
I_p = polar moment of inertia* of the cross section
= moment of inertia of cross section about the axis of the shaft
= $\Sigma t^2 a$, = the sum, for all the fibers, of $t^2 a$.................................in inches.

*In any figure, the polar moment of inertia, I_p, is = the sum of the greatest and the least moments of inertia of the same figure, about two axes lying in the figure and intersecting in its center. In a solid circle, each of these is a moment of inertia about a diameter, and is $= \pi T^4 \div 4$. Hence, in such a circle, $I_p = \pi T^4 \div 2$.

Then the unit stress, in any given fiber, is $s = S\,l \div T$; its total stress, F, is $= a\,s = S\,a\,l \div T$; and its resisting moment, r, is $= F\,l = S\,a\,l^2 \div T$. For equilibrium, the internal resisting moment, R, of the entire section, must be = the external torsional moment, M.

Hence, for the **Internal Resisting moment,** R, we have:

$R = M = \Sigma\, r = \Sigma\, S\,a\,l^2 \div T = (S \div T)\,\Sigma\, l^2\,a = (S \div T)\,I_p.$

Hence, also, $S = M\,T \div I_p$; $M = S\,I_p \div T$; and $P = M \div l = S\,I_p \div (T\,l)$.

In a solid circle, $I_p = \pi\,T^4 \div 2$. Hence, $S = 2\,M\,T \div (\pi\,T^4) = 2\,M \div (\pi\,T^3)$; $M = S\,\pi\,T^3 \div 2$; $P = S\,\pi\,T^3 \div (2\,l)$; and

$$\textbf{Diameter,}\ D, = 2\,T = 2 \times \sqrt[3]{\frac{2\,P\,l}{\pi\,S}} = \sqrt[3]{\frac{5.1\ M}{S}} = 1.72\,\sqrt[3]{\frac{M}{S}}.$$

For approximate ultimate values of S, for torsion, use the values for shearing, p 499, with **safety factors** from 5 to 10.

Horse power of shafting. In one revolution, the force, P lbs, describing a circle with radius l ins, does a work $2\,\pi\,l\,P$ inch-lbs, and, in n revolutions, work $= 2\,\pi\,l\,P\,n$ inch-lbs. If n be the number of revolutions *per minute*, the horse power is:

$H = 2\,\pi\,l\,P\,n \div (12 \times 33{,}000) = 2\,\pi\,M\,n \div (12 \times 33{,}000)$;

or, since $P\,l = M = R = S\,I_p \div T$, we have:

$H = S\,\pi\,n\,I_p \div (12 \times 16{,}500\,T)$; and $S = 12 \times 16{,}500\,T\,H \div (\pi\,n\,I_p)$.

In a solid cylindrical shaft, $I_p = \pi\,T^4 \div 2$. Hence,

$H = S\,\pi\,n\,\pi\,T^4 \div (12 \times 33{,}000\,T) = S\,\pi^2\,n\,T^3 \div (12 \times 33{,}000)$;

$S = 12 \times 33{,}000\,H \div (\pi^2\,n\,T^3) = 12 \times 3{,}343\,H \div (n\,T^3)$;

$n = 321{,}000\,H \div (D^3\,S)$; and

$$\textbf{Diameter,}\ D = 2\,T = 2 \times \sqrt[3]{\frac{12 \times 3{,}343\,H}{S\,n}} = \sqrt[3]{\frac{321{,}000\,H}{S\,n}} = 68\,\sqrt[3]{\frac{H}{S\,n}}.$$

The higher the speed, the less is the force, and hence the less is the strength of shaft, required in order to transmit a *given horse-power*; but if the speed is increased by increasing the torsional force, the horse-power transmitted is thereby increased also.

Example. Given, a wrought iron shaft; let S = 6,000 lbs per sq inch; P = 7,500 lbs; l = 10 ins; M = 75,000 inch-lbs. Required the diameter, D. Here, $D = 1.72 \times \sqrt[3]{M \div S} = 1.72 \times \sqrt[3]{75{,}000 \div 6{,}000} = 1.72 \times \sqrt[3]{12.5} = 1.72 \times 2.32 = 4$ ins. Let the horse-power, H, = 25. Then $n = 321{,}000\,H \div (D^3\,S) = 321{,}000 \times 25 \div (4^3 \times 6{,}000) = 21$ revolutions per minute. Checking, $D = 68 \times \sqrt[3]{H \div (S\,n)} = 68 \times \sqrt[3]{25 \div (6{,}000 \times 21)} = 68 \times 0.058 =$ say 4 inches.

Rectangular Sections. The foregoing equations are based upon the assumption that the stress increases uniformly from the axis of the shaft outward. It has been shown (notably by St. Venant*) that this assumption is not applicable to square and rectangular sections. In a rectangle, let B = the longer, b = the shorter side, and $c = b \div B$. Then $S = M\,(3 + 1.8\,c) \div (B\,b^2)$; and $P = S\,B\,b^2 \div [(3 + 1.8\,c)\,l]$. In a square, with side $= b$, this becomes: $S = 4.8\,M \div b^3$; $M = S\,b^3 \div 4.8$. $P = S\,b^3 \div (4.8\,l)$.

The angle of torsion is that described by one of the external torsional moments, relatively to the other. Within the elastic limit, this angle is proportional to the torsional moment, M, and (assuming l constant) proportional to the force, P. Other things being equal, the angle is proportional to the distance between the planes of the two contrary external moments, and, in a solid cylindrical shaft, is inversely proportional to D^4. It is inadvisable to allow the angle of torsion to exceed 1° in a length = 20 diameters, in shafts revolving in one direction. In reciprocating shafts allow still less. See Fatigue, p 465.

Practical Considerations. In many cases the diameter of the shaft must be made greater than that required by the foregoing formulas; as in a long shaft, in order to keep the angle of torsion within permissible limits; in fly-wheel and other shafts, carrying considerable bending loads in addition to the torsion; and, in most cases, to allow for additional moments due to alternate acceleration and retardation.

---

*See Treatise on Natural Philosophy, by Sir William Thomson and Peter Guthrie Tait, Part II, New Edition, Cambridge, 1890, pp 236, etc.

HYDROSTATICS.

Art. 1. Hydrostatics treats of the pressure of water and of other fluids at rest.

At any given point within a fluid **the pressure is equal in all directions;** and the pressure against any point of any surface, whether plane or curved, is **normal to the pressed surface** (or to a plane tangent to that surface) at that point.

The intensity of the pressure is proportional to the depth of the point below the water surface.

Pressure against any plane surface.

Let

a = the area of the pressed surface;
h = the vertical depth of the center of gravity of the pressed surface below the free surface of the fluid;
H = the total depth of the fluid;
w = the weight of a unit volume of the fluid;*
p = the mean unit pressure on the pressed surface;
P = the total pressure on the pressed surface;

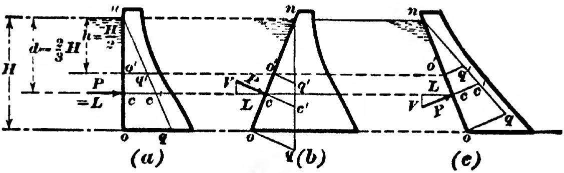

Fig. 1.

Then the **mean unit pressure,** p, is equal to the weight of a prism of the fluid, whose base is = 1, and whose length is = h; or

$$p = h\,w;$$

and the **total pressure,** P, is equal to the weight of a prism of the fluid, whose base is = a, and whose length is = h. Or

$$P = a\,h\,w = a\,p.$$

In the diagrams of Figs. 1 and 2, the *ordinates* (supposed to be drawn from, and normally to, the pressed surfaces respectively) represent the *unit* pressures (as in lbs. per sq. inch, kilograms per sq. centimeter, etc.), and the *area*, opposite any given surface, represents the *total* pressure on that surface. Thus, in Fig. 1 (a), the unit pressures at n, at o', at c and at o, are represented by n (= 0), by $o'\,q'$, by $c\,c'$ and by $o\,q$ respectively; and the total pressure on $n\,o$ is represented by the area $n\,o\,q$, that on $n\,o'$ by the area $n\,o'\,q'$, that on $o'\,o$ by the area $o\,q'$, and that on $o'\,c$ by the area $c\,q'$.

The center of pressure upon any surface is opposite the center of gravity of the area representing the total pressure upon that surface. Thus, in Figs. 1, the center of pressure on $n\,o$, is opposite the center of gravity of the triangle, $n\,o\,q$, or at a depth, d, = $\frac{2}{3}$ H, below the water surface. See The Center of Pressure, Arts 8, etc., also ¶¶ 133 etc., of Statics.

The hydrostatic paradox. For a given depth, h, both the mean unit pressure, p, and (for a given area, a) the total pressure, P, are independent of the quantity of water. Thus, in Figs. 1, the walls sustain as great a pressure from a vertical film of water only an inch thick, as if the water extended back

* For water, w = about 62.5 lbs. per cub. ft., = about 0.0362 lbs. per cub. inch.

for miles. In Fig. 2 (*b*), the excess of weight of water, over that in Fig. 2 (*a*), is carried by the lower sloping *wall* of the vessel. The total pressures, P, upon the equal bases, *a b* and *a' b'*, Figs. 2 (*c*) and (*d*), are equal. In Fig. 2 (*c*), the total pressure upon the base is greater, and in Fig. 2 (*d*) less, than the weight of the water; but, in either case, the algebraic sum of all the vertical pressures in the vessel (*upward* pressures taken as *negative*) is = the weight of all the water in the vessel; and the algebraic sum of all the horizontal pressures is = 0.

Thus, let the lower part of Fig. 2 (*c*) represent a cubical box, 8 feet on a side, and filled with water. Now let the tube, *n o*, 36 ft. high and of 0.287 inch bore, be filled with water. The water in the tube alone, although weighing only about 1 pound, will cause an additional bursting pressure of 2250 lbs. per square foot, or say 384 tons total, to be exerted upon the top, bottom and sides of the box.

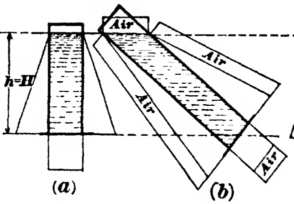

Fig. 2.

Air pressure on water surface. In addition to the pressure of the water itself, the free surface of any body of water sustains also the pressure of the air, = about 14.7 lbs. per sq. inch. This pressure (transmitted through the water to the walls of the vessel) is indicated by the diagrams (parallelograms) marked "air" in Fig. 2 (*b*). In most cases, the pressure against a surface, due to the air pressure on the water surface, is counter-balanced by an equal pressure of the air in the opposite direction, as against the outer sides of the walls of the vessels in Figs. 2, and against the down-stream sides of the dams in Figs. 1.

Strictly speaking, the air pressure, exerted directly against the walls, Fig. 2, or against the dams, Figs. 1, being exerted practically at the centers of gravity of those surfaces, and therefore at lower elevations than the opposite pressure due to the air pressure on the water surface, is a very little greater than the latter. In a dam 100 ft deep, this difference would amount to about 0.027 lb per sq inch, = 0.0018 atmosphere.

Braces for dams. The water pressure being normal to the pressed surface, the posts, Fig. 3, must also be normal to the surface, D, if they are to receive

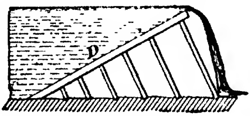

Fig. 3.

that pressure longitudinally and thus avoid bending moments; but other considerations may forbid their being so placed. Thus, if the face, D, of the dam, is nearly vertical, the posts would have to be made inordinately long; and their consequent weakness, as pillars (unless made inconveniently thick) might more than offset the advantage due to directness of pressure. Moreover, the feet of the down-stream posts would project beyond the crest of the dam, and would thus be liable to injury by ice or logs, etc., tumbling over the dam.

Inasmuch as the pressure increases uniformly from the water surface downward, the posts are usually placed closer together near the bottom than near the top, although the shortness of the lower ones renders them stronger as pillars. Similarly, the hoops on tanks, if of uniform strength, are placed closer together near the bottom.

Horizontal and vertical components. In Figs. 1 (*b*) and (*c*), the force triangle (Statics, ¶¶ 46, etc.) gives us the horizontal and vertical components, L and V, of the total normal pressure, P. Or, if *n o* be taken, in each case, as representing the total normal pressure, P, by scale, then H = the total horizontal pressure. In Fig 1 (*a*), with pressure against a vertical surface, L = P, and V = 0.

In Fig. 1 (*b*), the vertical component, V, presses the wall downward against its base, but in Fig. 1 (*c*) it tends to uplift and overturn it.

The depth, H, being the same in each of the three figures, Figs. 1 *a*, *b* and *c*, the *vertical* projections of the three submerged surfaces are equal, and hence the total *horizontal* pressures are equal in the three cases; but the *horizontal* projection, and consequently the total *vertical* pressure, vary with the inclination of the surface. Thus, in Fig. 1 (*a*), the horizontal projection and the vertical pressure are each = 0.

Pressures in cubical and other vessels, full of water. Let F = the weight of water contained in a prismatic vessel; and $f = \frac{F}{3}$ = the weight of that in a conical or pyramidal vessel of the same base and height.

In a cubical vessel, pressure on base = F; pressure on one side = $\frac{F}{2}$; pressure on base and four sides together = $F + 4\frac{F}{2} = 3\,F$.

In a conical or pyramidal vessel, pressure on base = $3\,f$ = F.

In a spherical vessel, total pressure = 3 × weight of water.

Art. 2. Unequal pressure in opposite directions. In Figs. 4, let *n o* represent the edge of a parallelogram, whose top coincides with the water surface, and whose bottom is parallel with that surface; let *a* = the area of that portion, *n' o*, which is subjected to pressure on both sides; and let H and

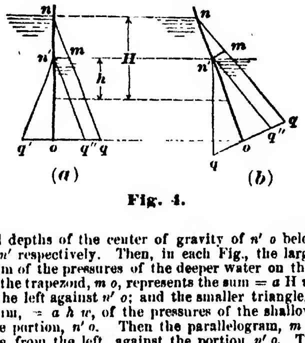

Fig. 4.

h = the vertical depths of the center of gravity of *n' o* below the two water surfaces, *n* and *n'* respectively. Then, in each Fig., the large triangle, *n o q*, represents the sum of the pressures of the deeper water on the left against the entire wall, *n o*; the trapezoid, *m o*, represents the sum = *a* H *w*, of the pressures of the water on the left against *n' o*; and the smaller triangle, *n' o q'*, = *n' o q''*, represents the sum, = *a h w*, of the pressures of the shallower water on the right against the portion, *n' o*. Then the parallelogram, *m q''* represents the *excess* of pressure, from the left, against the portion, *n' o*. This excess, due to the difference, H — *h*, between the two levels, is *uniformly* distributed over *n' o*, the uniform excess *unit* pressure being represented by the ordinate *n' m* = *q'' q*. The *total* excess pressure, represented by the parallelogram, *m q''* = *a* H *w* — *a h w* = (H — *h*) *a w*, is therefore proportional to H — *h*.

The pressure coming from the right against the portion *n' o*, and represented by the triangle *n' o q'*, is balanced by an equal portion (represented by the triangle *n' o q''*) of the total pressure, *m o*, from the left against the portion *n' o*; and the centers of these two pressures, each being at a depth = ⅔ *n' o* below *n'*, are opposite. Hence these two pressures are in equilibrium. But the center of the excess pressure, *n' q*, from the left, is opposite the center of gravity of the parallelogram, *n' q*, or at the center of gravity of *n' o*. Hence the portion *n' o*, considered independently of *n' n*, is acted upon by the unbalanced force *n' q*, coming from the left, acting through its center of gravity and therefore tending to move it bodily toward the right, without rotation.

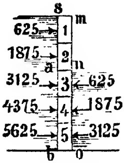

Fig 5

This will be understood by means of Fig 5 which may represent five planks, 1, 2, 3, 4, and 5, forming a dam, and seen endwise, each one 1 ft in depth, and say 20 ft long hor, making the area of each surf pressed, equal to 20 sq ft. The pres in lbs against each separate 20 sq ft of area, calculated by the rule in Art 1, is shown in the fig Now, the outward pres against the upper *immersed* 20 ft area, or that of plank 3, is 3125 lbs, while the counter-pres against it from the other side is 625 lbs, making the *excess* of outward pres equal to 3125 — 625 = 2500 lbs. Again, at the lowest plank, number 5, the outward pres exceeds the inward one by 5625 — 3125 = 2500 lbs, the same as in the upper one And so of any other equal area of surf, at any depth whatever; the excess depending upon the vert height of *m n*, will be equally distributed over *a b*. It only remains to show that the total excess of outward pres against *a b*, is equal in amount to the wt of a uniform column of water with a base equal in area to *a b*, and with a height equal to *m n* * Thus, we have seen that in the instance before us, the excess amounts to 3 times 2500 lbs, or to 7500 lbs. Now, the wt of the column of water will be 60 (or area of *a b*) × *m n* (or 2 ft; × 62.5 lbs = 7500 lbs; or the same as the *excess* pres on *a b*

The excess of pres against the entire side *s b*, over that against *n o*, is evidently the diff between those two pressures calculated respectively by the rule in Art 1.

Art. 3. Surfaces, vert, as *b m c s*, *a n o t*, Fig 6, or otherwise, of equal widths, *b m*, *a n*; commencing at the level, *b a n m*, of the water, but extending to diff depths, *m c*, *n o*, measured vert; and having the same inclination to the surf of the water; sustain total pressures proportional to the squares of those depths.

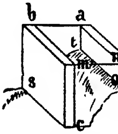

Fig 6

In Fig 6, let the two vert sides, *a n o t*, and *b m c s*, of a vessel, have the same width *a n*, and *b m*, then if the depth *m c*, be 2, 3, 4 5, &c times greater than the depth *n o*, the pres against the surf *b m c s* will be 4, 9, 16, 25, &c, times greater than that against *a n o t* This will be seen by referring to the pressures figured on the left side of Fig 5, where, as stated in Art 2, the surf of plank 1, exposed to the pres on the left side, is 20 sq ft, that of planks 1 and 2, 40 sq ft, that of planks 1, 2, and 3, 60 sq ft, &c All these surfs commence at the level of the water, and all of them being vert are of course at the same inclination with the water surf, but their depths are respectively 1, 2, and 3 ft The pres against the surf of 1, is 625 lbs; that against the surf of 1, 2, is 625 + 1875 = 2500, and that against the surf of 1, 2, 3, is 625 + 1875 + 3125 = 5625 But 2500 is *four* times 625, and 5625 is *nine* times 625. And the pres against the entire surf *s b*, (which is 5 times as deep as plank 1,) is 25 times as great as that against plank 1, or 625 × 25 = 15625 lbs = the sum of all the pressures marked on the left side of Fig 5

This follows, from the Rule in Art 1, for twice the area of surf, mult by twice the vert depth of the cen of grav below the surf, must give 4 times the pres, three times the area, by three times the depth, must give 9 times the pres, &c.

It follows, also, that at any particular *point*, or against any *given* area placed at various depths, the pres will increase simply as the vert depth thus, if there be three areas, each one sq ft, placed in the same positions, but with their centers of grav respectively 8, 16, and 24 ft below the surf, the pres against them will be respectively *as* 8, 16, and 24, or *as* 1, 2, and 3

Art. 4. The pressure of quiet water, in any one given direction, against any given plane surface, whether vertical, horizontal, or inclined, is equal to the weight of a prismatic column of water, the area of whose section, parallel to its base, is equal to the area of the projection of the given surface taken at right angles to the given direction, and whose height is equal to the vertical depth of the center of gravity of the given surface below the upper surface of the water. Hence the

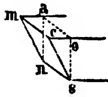

Fig 7

RULE **To find the pres in lbs,** mult together the area in sq ft of the projection taken at right angles to the given direction; the vert depth in ft of the cen of grav of the pressed surf below the upper surf of the water, and the constant 62.5 lbs wt of a cub ft of water.

Ex. Let *m c s n*, Fig 7, be an inclined surf, sustaining the pres of water which is level with its top *m c* Then the *total* pres against *m c s n*, and at right angles to it, as found by the rule in Art 1, is an illustration of the present rule; because the projection of *m c s n*, taken at right angles to the given direction, or parallel to *m c s n*, is in fact *m c s n* itself, or equal to it Hence the rule in Art 1 is merely a simple modification of the present one, applicable to the case of *total* pres against any surf.

But if it be reqd to find only the vert or downward pres against *m c s n*, in pounds, mult together the area of the hor projection *a o c m* in sq ft; the vert depth in ft of the cen of grav of *m c s n* below the surf, and 62 5. Or if only the *hor* pres against *m c s n* be sought, mult together the area of the vert projection *a o s n*; the vert depth of the cen of grav of *m c s n*, and 62 5.

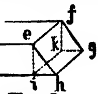

Fig 8

In Fig 8 also, the *total* pres against *e f g h* is found by rule in Art 1; while the *hor* and vert pressures against it are found as in Fig 7, by using the projections *e f k i*, and *k i g h*. In Fig 7 the vert pres is downward; while in Fig 8 it is upward, but this circumstance in no respect affects the rule.

REM. 1. At any given depth, the pres, perp to any given surf, is the same in all directions; but Figs 7 and 8 show that the total pres *oblique* to a given surf will be less than the perp one at the same depth; because an oblique projection of a surf must be less than the surf itself, which last is the projection when the pres is perp to it. Thus, in a reservoir, the total pres perp to a sloping side, as *m n s s*, Fig 7 is *greater* than either the vert or the hor pres upon it.

Again, let Fig 9 represent **a conical vessel full of water;** its base $b\ c$, 2 ft diam; its vert height $a\ n$, 3 ft, then the circumf of the base will be 6.2832 ft, the area of the base 3.1416 sq ft, the length of its slant side $a\ b$ or $a\ c$, 3.16 ft, the area of its curved slanting sides will be $\frac{6.2832 \times 3.16}{2} = 9.93$ sq ft; and the vert depth of the cen of grav of the slanting sides will be at two thirds of the vert height $a\ n$ from the apex a, or 2 ft.

Fig 9

Here, to find the total pres against the base, we have by rule in Art 1, 3.1416 × 3 × 62.5 = 589.05 lbs. For the total pres against the slant sides, by the same rule, 9.93 × 2 × 62.5 = 1241.25 lbs. For the vert pres upward against the entire area of the slant sides, we have given the area of the base (which is here the hor projection of the slant sides) = 3.1416, and the vert depth of the cen of grav of the slant sides, 2 ft. Therefore, 3.1416 × 2 × 62.5 = 392.7 lbs, the upward vert pres.

Finally, for the hor pres in any given direction against the slant sides of *one half* of the cone, we have the vert projection of that half, represented by the triangle $a\ b\ c$, with its base 2 ft, and its perp height 3 ft, and consequently, with an area of 3 sq ft. The depth of its cen of grav is 2 ft; therefore, 3 × 2 × 62.5 = 375 lbs, the reqd hor pres.*

In Fig 10, which represents a vessel full of water, the *total* pres against the semi cylindrical surf $a\ v\ e\ m\ d\ k$, and perp to it, must be also hor, because the surf is vert, but inasmuch as the surf is *curved*, this total pres, as found by rule in Art 1, acts against it in many directions, which might be represented by an infinite number of radii drawn from o as a center. But let it be reqd to find the hor pres in lbs, in one direction only, say parallel to $o\ e$, or perp to $a\ d$; which would be the force tending to tear the curved surf away from the flat sides $a\ b\ n\ i$, and $d\ c\ s\ k$, by producing fractures along the lines $a\ v$ and $d\ k$, or which would tend to burst a pipe or other cylinder. In this case, mult together the area of the vert projection $a\ d\ k\ v$ in sq ft, the depth of the cen of grav of the curved surf in ft, (which, in the semi cylinder would be half of $e\ m$, or of $o\ i$,) and 62.5. Since the resulting pres is resisted equally by the strength of the vessel along the two lines $a\ v$ and $d\ k$, it is plain that each single thickness along those lines need only be sufficient to resist safely *one half* of it. and so in the case of pipes, or other cylinders, such as hooped cisterns or tanks. See Art 17.

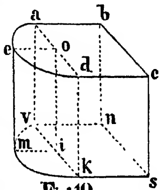

Fig 10

Should the pres against only one half of the curved surf, as $e\ d\ m\ k$ be sought, and in a direction parallel to $o\ d$, tending to produce fractures along the lines $e\ m$, and $d\ k$, then use the vert projection $o\ e\ m\ i$, with the same depth, and 62.5 as before.

It follows, that if the face of a metallic piston be made concave or convex, no more pres will be reqd to force the piston through any dist, than if it were flat, for the pres against the face of the piston, in the direction in which it moves, must be measured by the area of a projection of that face, taken at right angles to said direction, and the area of said projection will be the same in all three cases.

REM 2. **If a bridge pier, or other construction, Fig 10½, be founded on sand or gravel,** or on any kind of foundation through which water may find its way underneath, even in a very thin sheet, then the upward pres of the water will take effect upon the pier, and will tend to lift it, with a force equal to the wt of the water displaced by the pier; (Arts 18, 19.) In other words, the effective wt of the *submerged* portion of the pier, will be reduced 62½ lbs per cub ft; or nearly the half of the ordinary wt of masonry.

Fig 10½

But if the foundation be on rock, covered with a layer of cement to prevent the infiltration of water beneath the masonry, no such effect will be produced but on the contrary, the vert pres downward, afforded by the battering sides of the pier, and by its offsets, will tend to hold it down, and thus increase its stability; which, in *quiet* water, will then actually be greater than on land.

Art. 5. To divide a rectangular surf, whether vert as *a b c d*, or inclined as *m n o p*, Fig 11, whose top *a b* or *m n* is level with the surf of the water, by a hor line *x* 2, such that the total pres against the part above said hor line, shall equal that against the part below it.

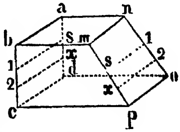

Fig 11

RULE. Mult one half of the length of $b\ c$, or $m\ p$, as the case may be, by the constant number 1.4142, the prod will be b 2, or $m\ x$.

Ex. Let $b\ c$ = 12 ft. Then 6 × 1.4142 = 8.4852 ft, or b 2. Let $m\ p$ = 16 ft. Then 8 × 1.4142 = 11.3136 ft, or $m\ x$.

REM. The line x 2, thus found, must not be confounded with the *cen of pres* which is entirely diff. See Art 8.

Art. 6. In a rectangular surf, whether vert as *a b c d*, or inclined as *m n o p*, Fig 11, whose top *a b* or *m n* coincides with the surf of the water, to find any number of points, as 1, 2, &c, through which if hor lines, as 1 *s*, 2 *x*, &c, be drawn, they will divide the given surf into smaller rectangles, all of which shall sustain equal pressures.

RULE. First fix on the number of small rectangles reqd. Then for point 1 from the top, mult the number 1, by this number of rectangles. Take the sq rt of the prod. Mult this sq rt by the entire length

* **In a sphere** filled with a fluid the total inside pres = 3 times wt of fluid.

$b\,c$ or $m\,p$, as the case may be. Div the prod by the number of rectangles. The quot will be the dist b 1, or n 1, as the case may be.

For the dist b 2, or n 2, proceed in precisely the same way, only instead of the number 1, use the number 2 to be mult by the number of rectangles· and so use successively the numbers 3, 4, 5, &c, if it be reqd to find that number of points

Ex. Let $b\,c = 10$ ft; and let it be reqd to find 2 points, 1 and 2, for dividing the rectangular surf $a\,b\,c\,d$ into 3 rectangular parts, which shall sustain equal pressures. Here we have for point 1,

$1 \times 3 = 3$ The sq rt of $3 = 1.732$. And 1.732×10 (or $b\,c$) $= 17.32$. And $\dfrac{17.32}{3 \text{ rectangles}} = 5.773$ ft $= b$ 1.

For point 2, we have

$2 \times 3 = 6$. The sq rt of $6 = 2.449$. And 2.449×10 (or $b\,c$) $= 24.49$. And $\dfrac{24.49}{3 \text{ rectangles}} = 8.163$ ft $= b$ 2.

And so for any number of points.

REM. 1. **This rule will be found useful in spacing the cross-bars of lock-gates; the hoops around cylindrical cisterns: and the props to a structure, like Fig 3.**

REM. 2. **For dividing any surf, as $o\,b\,c\,d$, Fig 12, which is not rectangular, in the same manner,** with an accuracy sufficient for most practical purposes, perhaps the following method is as convenient as any.

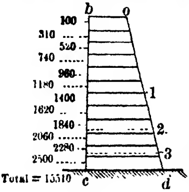

Fig. 12.

RULE. First div the surf, as in Fig 12, into several small hor parts, equal or not, at pleasure. Then by Rule in Art 1, find the pres on each part separately, as is supposed to be done in the numbers on the left hand of the fig The sum of these (in this case 15510) is the total pres against the entire surf $o\,b\,c\,d$. Now suppose we wish to div this surf in 4 parts bearing equal pres; first div 15510 by $4 = 3878$. Then beginning at the top, add together a number of the separate pressures sufficient to amount to 3878, by this means find point 1. Then proceed with the addition until the sum amounts to twice 3878, or 7756, which will indicate point 2, and in the same manner find point 3, by adding up to three times 3878, or 11634 Then the hor dotted lines ruled through points 1, 2, and 3, will give the reqd divisions approximately. In this manner the hoops of conical, and other shaped vessels, may be spaced nearly enough for practical purposes.

Art. 7. The transmission of pressure through water. Water, in common with other fluids, possesses the important property of transmitting pres equally in all directions. Thus, suppose the vessel, Fig 13, to be entirely closed, and filled with water; and suppose the transverse area of T, C, D, and E, to be each equal to one sq inch. Then, if by means of a piston, or otherwise, a pres of 1 ℔, 1 ton, or any other amount, be applied to the one sq inch of area of T, C, D, or E, every sq inch of the inner surf of the vessel, and of the pipe a, will instantly receive, at right angles to itself an equal pres of 1 ℔, or 1 ton, &c, in addition to the pres which it before sustained from the water itself, and this will occur if the vessel consist of parts even miles asunder; as, for instance, if T were miles distant from E; and united to it by a long series of tubes. If the vessel were a strong steam boiler full of water, a single pres of a few hundred pounds at T, C, &c, would burst it. See also Fig 2 (c) and paragraph above it.

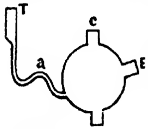

Fig. 13.

The hydrostatic press acts on this principle. Any body, within the vessel, would also receive an equal additional pres on each sq inch of its surf.

If the top of T be open, the air will press upon the sq inch of the exposed surf of water to the extent of nearly 15 ℔s; and the same degree of pres will also be transmitted to every sq inch of the interior surf of the vessel, and its connecting tubes; but no danger of bursting will result from this atmospheric pres, because the air also presses every sq inch of the outside of the vessel to the same extent.

Air, and other gaseous fluids, transmit pres equally in all directions, like liquids; but not as rapidly.

Art. 8. The center of pressure. Let Fig 14 represent a vessel full of water, and suppose the side P to be perfectly loose, so as to be thrown outward by the slightest pres of the water from within. Now, there is but one single point, P, in every surf so pressed, no matter what its shape may be to which if we apply a force equal to the pres of the water, and in a direction opposite to said pres, the side P will be thereby prevented from yielding Such point is called the *center of pressure.* It must not be understood by this that the actual amount of pres of the water against that part of the surface which is above the hor dotted line passing through P, is equal to that of the water below said line; but that the sum of the products of the several pressures above it, mult by their several leverages, or vert dists from P, is equal to the sum of the products of the pressures below, mult by their leverages; or, in other words, that the sum of the *moments* around the point P, of the pressures above the line, is equal to the sum of the *moments* of those below it; so that if a hor iron rod $b\,b$ were passed entirely through the side P, at the same level as the dotted line, as shown in the fig, so as to serve as a hinge for the side P to turn on, the side would have no tendency to turn.

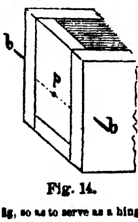

Fig. 14.

Art. 9. To find the cen of pres of a quiet fluid, against a plane surface. Fig 15.

1. The center of pressure of a quiet fluid against any plane surface whose width is uniform throughout its depth, whether said surface be vertical, as *e o*, or inclined, as *c a*, (or inclined in the opposite direction:) and whose top *c*, or *e*, coincides with the hor water surf, is distant *vert* below the water surf, two-thirds of the vert depth, *s x*, from said water surf to the bottom of the plane, as at *n* and *i*. Inasmuch as a hor line at ⅔ of the depth of *s x*, intersects both *c a* and *e o* at ⅔ of their lengths respectively, we might say at once that the center of pres against a plane parallelogram, with its top at the water surface, is at two-thirds of its length below the water surface.

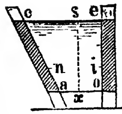

Fig. 15

Throughout Art 9 **any measure,** as yard, foot, or inch &c, may be used.

2. But if the hor top *a*, or *o*, Fig 16, of the rectangular plane *a g*, or *o h*, be covered to some depth with water, then the *vert* depth *s m*, of the cen of pres *d*, or *e*, below the surf of the water, will be equal to

$$\tfrac{2}{3} \text{ of } \frac{\text{cube of } sc - \text{cube of } sw}{\text{square of } sc - \text{square of } sw}$$

where *s c* is the vert depth of the bottom, and *s w* the vert depth of the top, of the pressed surf, below the water surf. Or, in words From the cube of *s c*, take the cube of *s w*, and call the rem *a*. Then, from the square of *s c*, take the square of *s w*; and call the rem *b*. Div *a* by *b*, and take two thirds of the quot for *s m*.

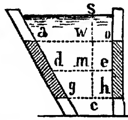

Fig. 16.

3. When a plane surf of any shape whatever, whether rectangular, triangular, or circular, &c, whether vert as *o p*, Fig 17, or inclined as *m n*, is *entirely immersed*, so as to be pressed over the entire area of *both* sides but by *diff depths* of water on its two sides, then the cen of pres coincides with the *cen of grav* of the pressed surf.

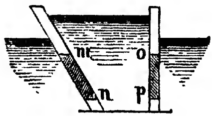

Fig. 17.

In the 3 foregoing figures the supposed surfaces are shown edgewise, so that their widths do not appear.

4. In any triangular plane surf, whether right-angled, or otherwise, as *a b c*, Fig 18, whether vert, or inclined; the *base* *a b* of which coincides with the hor surf of the water, the cen of pres *o*, will be in the center of the line *c r*, which bisects the base *a b*.

5 But if the triangle, as *a s c*, vert, or inclined, have its *apex*, *a*, at the surf of the water; and its base *s c*, *hor*; then the cen of pres *x*, will also be in the line *a m* which bisects the base; but *a x* will be ¾ of *a m*.

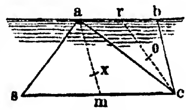

Fig. 18.

6 If any plane triangle *a b c*, Fig 19, base up, and hor, have its base *a b* covered to some depth *n d*, with water, then the cen of pres *o*, will be in the line *c s* which bisects the base; and *n o* will be equal to

$$\frac{mx^2 + (2mx \times ma) + 3ma^2}{(mx + 2ma) \times 2.}$$

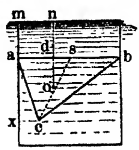

Fig. 19.

7. The center of pres against any plane *rectangular* surface, Fig 20, whether vert as *m n*, or inclined as *p o*, or *w x*, having its top coinciding with the surf of the water; and pressed by diff depths of water on its opposite sides, as shown in the fig; will be *vert* below the *upper* water surf, a dist equal to

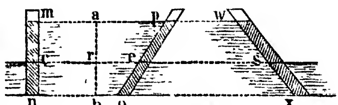

Fig. 20.

$$\frac{\left(\begin{array}{c}\textit{area of surf } \text{m n},\\ \textit{or } \text{p o}, \textit{or } \text{w x}\end{array} \times \frac{\textit{sq of vert depth } \text{a b}}{3}\right) - \left(\begin{array}{c}\textit{area of surf}\\ \text{c n}, \textit{or } \text{e o}, \textit{or } \text{s x}\end{array} \times \frac{\textit{sq of vert depth } \text{r b}}{3}\right) - \left(\begin{array}{c}\textit{vert depth}\\ \text{a r}\end{array} \times \begin{array}{c}\textit{area of surf } \text{c n},\\ \textit{or } \text{e o}, \textit{or } \text{s x}\end{array} \times \frac{\textit{vert depth } \text{r b}}{2}\right)}{\left(\begin{array}{c}\textit{area of surf}\\ \text{m n}, \textit{or } \text{p o}, \textit{or } \text{w x}\end{array} \times \textit{half of } \text{a b}\right) - \left(\begin{array}{c}\textit{area of surf}\\ \text{c n}, \textit{or } \text{e o}, \textit{or } \text{s x}\end{array} \times \textit{half of } \text{r b}\right).}$$

9. To find the center of pressure against either a circular or an elliptic surface, pressed on one side only; whether vertical or inclined, and having its top either coinciding with the surface of the water or below it.

Let h = the vertical depth of the center of pressure below the water surface.
r = the vertical or inclined *semi*-diameter of the surface.
d = the *vertical* distance of the *center* of the pressed surface, below the water surface.

Then

$$h = \frac{r^2}{4d} + d.$$

In a **vertical circle,** with top at water surface, $h = 1\frac{1}{4} \times$ radius.

Art. 10. Walls for resisting the pressure of quiet water. A study of our remarks on retaining-walls for earth, pp. 603, etc, will be of use in this connection. It is of course assumed that the water does not find its way under the wall; and that the wall cannot slide. In making calculations for walls to resist the pressure of either earth or water, it is convenient to assume the wall to be but one foot in *length* (not height, or thickness), for then the number of cubic feet contained in it, is equal to that of the square feet of area of its cross-section, or profile; so that these square feet, when multiplied by the weight of a cubic foot of the masonry, give the weight of the wall. In ordinary cases, it is well, for safety, to assume that the water extends down to the very bottom line of the wall.

Now, by Art 1, the total pressure of quiet water, against the rectilineal back of a wall, whether vertical or sloping, is found in lbs, by multiplying together the area in square feet of the part actually pressed, (or in contact with the water;) half the *vertical* depth of the water, in feet, (being the *vertical* depth of the center of gravity of a rectilineal back, below the surface); and the constant 62.5 lbs; and this total pressure is always *perpendicular to the pressed area.*

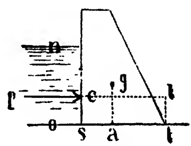

Fig 20½.

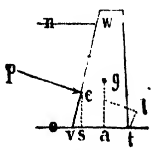

Fig 21.

When the back of the wall is vertical, as in Fig 20½, this pressure p is of course less than when it is battered; and is also *horizontal;* and it tends to overthrow the wall, by making it revolve around its outer toe, or edge t. The center of pressure is at c; $c\,s$ being ⅓ the *vertical* depth $o\,n$; in other words, the entire pressure of the water, so far as regards overthrowing the wall as one mass, may be considered as concentrated at the point c; where it acts with an overthrowing leverage $t\,l$. The pressure in lbs, multiplied by this leverage in feet, gives the *moment* in foot-lbs of the overturning force. The wall, on the other hand, resists in a vertical direction $g\,a$, with a moment equal to its weight (supposed to be concentrated at its center of gravity g), multiplied by the horizontal distance $a\,t$, which constitutes the leverage of the weight with respect to the point t as a fulcrum. If the moment of the water is greater than that of the wall, the latter will be overthrown; but if less, it will stand.

In Fig 21 the overturning moment of the water is equal to its calculated pressure $p \times$ its leverage $t\,l$; while the moment of stability of the wall is equal to its weight $\times$ its leverage $a\,t$. By aid of a drawing to a scale, we may on this principle ascertain whether any proposed wall will stand. For we have only to calculate the pressure p, then apply it at c, and at right angles to the back; prolong it to l; measure $t\,l$ by the same scale. Then calculate the weight of wall; find its center of gravity g; draw $g\,a$ vertical, and measure the leverage $a\,t$. We then have the data for calculating the two moments.

If the water, instead of being quiet, is liable to waves, the wall should be made thicker.

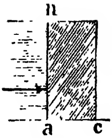

Fig. 22.

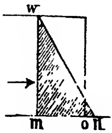

Fig. 23.

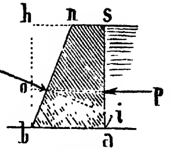

Fig. 24.

Art. 11. To find the thickness at base of a wall required to be safe against *overturning* under the pres of quiet water level with its top, and pressing against its entire vert back. **Caution.** See Art. 13.

(1st) Vertical wall, Fig 22.

$$\text{Thickness in feet} = \text{Height in feet} \times \sqrt{\frac{\text{Factor of safety *}}{3 \times \text{sp grav of wall}}} = \text{Height in feet} \times \text{the proper decimal in following table}$$

(2d) Right angled triangular wall, Fig 23.

$$\text{Thickness at base in feet} = \text{Height in feet} \times \sqrt{\frac{\text{Factor of safety *}}{2 \times \text{sp grav of wall}}} = \text{Height in feet} \times \text{the proper decimal in following table}$$

$$= \text{thickness, } m\,o\text{, of vertical wall} \times 1.225.$$

Notwithstanding their greater thickness at base, such triangular walls contain, as seen by the fig, not much more than half the quantity of masonry reqd for vert ones of equal stability. This is owing to the fact that their cent of grav is thrown farther back; thus increasing the leverage by which the wt of the wall resists overthrow.

(3d) Wall with vertical back and sloping face, Fig 24.

$$\text{Thickness at base in feet} = \sqrt{\frac{(\text{Ht}^2, \text{ft} \times \text{factor of safety *}) + (\text{batter } h\,n^2, \text{ft} \times \text{sp grav of wall})}{3 \times \text{specific gravity of wall}}}$$

$$= \text{Height in feet} \times \text{the proper decimal in the following table.}$$

$$\text{* Factor of safety} = \frac{\text{Required moment of stability of wall}}{\text{overturning moment of water}}.$$

Art. 12. Table showing how the stability of a wall sustaining water is affected by a change in the form of the wall; the quantity of masonry remaining the same. REM. When the base of a triangular wall, of sp grav 2, is less than ½ the ht, the stability is greatest when the water presses the vert side; but if the base exceeds ½ the ht, the stability is greatest with the water on the battered side. **Caution.** See Art. 13.

	All these walls contain precisely the same quantity of masonry. The masonry is supposed to be mortar rubble, weighing 125 lbs per cubic foot; or twice as much as water; or about the same as ordinary rough mortar rubble. If the sp gr of the masonry is actually greater or less than this, the safety also will be greater or less, in precisely the same proportion.	Base in parts of height	Approx resist of wall

Art. 13. Liability of wall or foundation to crush under unequal distribution of pressure. Arts 11 and 12 apply only to the *stability* of a *rigid* wall resting upon a *rigid* base, and therefore incapable of failure *except by overturning as a whole.* They show that the *stability* is greatest when the water presses against the *sloping* side. But in practice the point where the resultant of all the pressures on the base of the wall cuts the base, must not be so near to either toe as to endanger a *crushing* of wall or of foundation. This consideration often makes it best to let the water press against the *vert* back, notwithstanding the consequent loss in stability.

Art. 14. Fig. 25 shows, to scale, a dam wall at Poona, India, designed by Mr. Fife, C. E., of England. It is of mortar rubble, of 150 lbs per cub ft. Its total vert height is 100 ft; thickness *uv* at base, 60 ft 9 ins; at top, *rx*, 13 ft 9 ins. The front *ru* slopes 42 ft in 100 ft; and the back *xv*, 5 ft in 100 ft. Its foundation is 7 feet deep; but we here assume that the water presses against its *entire* back *xv*. Through the cen of grav G draw G*s* vert. From *c*, where the direction of the pres P of the water strikes G*s*, lay off *cn* by scale = 139.6 tons (of 2240 lbs) water pres against 1 ft in length of *xv*; and *ct* = 249.4 tons wt of 1 ft length of wall. Complete the parallelogram *cnmt* of forces. Its diag *cm* represents the resultant of all the pressures upon the base *uv*, and cuts the base at *a*, 20 ft back from the toe *u*. Doing the same with the 151.4 tons pres *p* against *ru*, we get the resultant *oy*, which is greater than *cm*, and cuts the base (at *i*) only 12.7 ft from the toe *v*, or 7.3 ft less than *a* is from *u*.

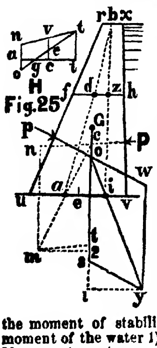

Fig. 25

Hence, when the water presses against *xv* the wall is less liable to fracture or crushing, and the earth foundation *uv* is more evenly loaded, and hence less liable to yield unequally so as to cause cracks in the wall. On this account *xv* is made the back of the wall, although the moment of stability of the wall is then only 2.2 (calling the overturning moment of the water 1), while if the water pressed against *ru* it would be 3, or 36 per cent greater.

Art. 15. The points a and i, Fig 25, are called **centers of pressure** upon the base, or **centers of resistance** of the base. If similar points, as d and z, be found in the same way for other lines, as fh, by treating a part (as $r\,x\,h\,f$) of the wall as if it were an entire wall; a slightly curved line joining these points is called the **line of pressure.** Thus, $b\,a$ is the line of pressure when the water presses against $x\,v$. Each point, as d, in $b\,a$, shows where any joint, as fh, drawn through that point, is cut by the resultant of all the forces acting upon said joint. $b\,i$ is the line of pres when the water presses against $r\,u$. These lines do not show the *direction* of the resultants Thus, at a, the latter is $c\,m$, not $b\,a$. The angle between the direction of the resultant and a line at right angles to the bed or joint, must be less than the angle of friction of the materials forming the joint.

If from the end m or y of the resultant of the pressures upon any joint, we draw $m\,2$ or $y\,l$ hor, then $c\,2$ or $o\,l$ (as the case may be) measures the entire *vert* pres on that joint: and $m\,2$ or $y\,l$ measures the *hor* pres against the back of the wall, which tends to cause sliding at the same joint If the direction of the resultant comes within the limit stated in the preceding paragraph, $m\,2$ or $y\,l$ will be less than the frictional resistance to sliding, which last is $= c\,2$ (or $o\,l$) $\times$ the coeff of friction for the surfaces forming the joint. Hence sliding cannot take place Sliding never occurs in the *masonry* of walls of ordinary forms. Good mortar well set aids to prevent sliding, but it is better not to rely upon it. But entire walls have slidden on slippery foundations.

Art. 16. In California, about 1860, were built dams of dry rough stone, founded on rock. Height 70 ft; base 90 ft; top 6 ft; hor spread of up-stream slope 70 ft; of outer slope 14 ft. Stone laid with some care by hand, except a core of about one-fifth of the mass, which was roughly thrown in. Water slope covered with 3-inch plank, laid hor on 12 × 12 inch stringers built into the stone work Cost about $3 per cubic yard. G. H. Mendell, Report on projects for San Francisco water supply, 1877, page 18.

Art. 17. To find the thickness of a cylinder to resist safely the pressure of water, steam, &c, against its interior. If riveted, see next page.

Where the thickness is less than one-thirtieth of the radius, as it is in most cases, the usual formula

$$\text{(1)}\qquad \underset{\text{in inches}}{\textbf{Thickness}} = \frac{\text{pressure}}{\text{safe strength}} \times \text{radius}^{*}$$

is employed. It regards the material as being subjected only to a direct tensile strain, which is sufficiently correct in such thin shells.

For somewhat greater pressures and thicknesses, Professor F. Reuleaux (Der Konstrukteur, p 52) gives

$$\text{(2)}\qquad \underset{\text{in inches}}{\textbf{Thickness}} = \frac{\text{pressure}}{\text{safe strength}}\left(1 + \frac{\text{pressure}}{2 \times \text{safe strength}}\right) \times \text{radius.}^{*}$$

For very great pressures and thicknesses, as in hydraulic presses, cannons, &c, Professor Reuleaux (Konstrukteur, p 53) gives Lamé's formula:

$$\text{(3)}\qquad \underset{\text{in inches}}{\textbf{Thickness}} = \left(\sqrt{\frac{\text{safe strength} + \text{pressure}}{\text{safe strength} - \text{pressure}}} - 1\right) \times \text{radius.}^{*}$$

The three formulæ give results as follows, pressures and strengths in lbs per square inch:

Diameter.	Radius.	Pressure.	Safe tensile strength.	Thickness, inches. Formula (1).	Formula (2).	Formula (3).
20 inches.	10 inches.	50	10000	**.05**	.050125	.05
"	"	500	"	.50	**.5125**	.513
"	"	5000	"	5.00	6 25	**7.32**

The thicknesses given by the formulæ appropriate to the several pressures are printed **in heavy type.** It will be seen that in these cases the results differ but slightly, except for *very* great pressures.

* In all three formulæ take the *radius in inches*, and the pressure and strength in *pounds per square inch.*

Rem. 2. Want of uniformity in the cooling of thick castings makes them proportionally weaker than thin ones, so that in order to reduce thickness in important cases we should use only best iron remelted 3 or 4 times, by which means an ult cohesion of about 30000 lbs per sq inch may be secured. But even with this precaution **no rule will apply safely** in practice to cast cylinders whose thickness exceeds either about 8 to 10 ins, or the inner rad however small

Under a pres of 8000 lbs per sq inch, **water will ooze through cast iron 8 or 10 ins** thick; and under but 250 lbs per sq inch, through .5 inch.

Table of thicknesses of single-riveted wrought iron pipes, tanks, standpipes, &c, by the above rule, to bear with a safety of 6 a quiet pressure of 1000 ft head of water, or 434 lbs per sq inch, the ult coh of fair quality plate iron being taken at 48000 lbs per sq inch, or at 8000 lbs for a safety of 6, which is farther reduced to 8000 × .56 = 4480 lbs, to allow for weakening by rivet holes; for **single-riveted** cyls have but about .56 of the strength of the solid sheet; and **double-riveted** ones about .7. With the above pres and other data, the rule here leads to thickness = .1016 × inner rad in ins.

Di. Ins.	Ths. Ins	Di Ins	Ths. Ins.	Di Ins.	Ths Ins	Di. Ins	Ths Ins.	Di Ins.	Ths Ins.	Di Ins	Di. Ft	Ths Ins.
.5	.025	5	.254	16	.813	30	1.52	60	3.05	120	10	6.09
1.0	.051	6	.305	18	.914	33	1.68	66	3.35	132	11	6.70
1.5	.076	8	.406	20	1.016	36	1.83	72	3.66	144	12	7.31
2.0	.102	10	.508	22	1.117	42	2.13	84	4.27	192	16	9.75
3.0	.152	12	.609	24	1.219	48	2.44	96	4.88	240	20	12.19
4.0	.203	14	.711	27	1.371	54	2.74	108	5.49	288	24	14.63

For a less head or pressure, or for any safety less than 6, it is safe and near enough in practice, to reduce the thickness of wrought iron cyls in the same proportion as said head, pres, or safety is less than the tabular one

Double-riveted cylinders, Fairbairn says, are about 1.25 times as strong as single-riveted. Hence they may be one-fifth part thinner **Lap-welded ones** are nearly 1.8 times as strong as single-riveted; and hence may be only .56 as thick.

Many continuous miles of **double-riveted pipes in California** have been in use for years with safetys of but 2 to 2.6. In one case the head is 1720 ft, with a pres of 746 lbs per sq inch, diam 11.5 ins; thickness, .34 inch.

Cast iron city water pipes must be thicker than required by formula (1), in order to endure rough handling and the effects of "water-ram" (due to sudden stoppage of flow, see second Rem, p 513), and to provide against irregularity of casting and the air bubbles or voids to which all castings are more or less liable. In the following table the ultimate tensile strength of cast iron is taken at 18,000 lbs per square inch. Column A gives thicknesses by Mr. J. T. Fanning's formula (Hydraulic Engineering, p 454).

$$\left.\begin{array}{l}\text{Thickness}\\ \text{in inches}\end{array}\right\} = \frac{(\text{pres, lbs per sq in} + 100) \times \text{bore, ins}}{.4 \times \text{ultimate tensile strength}} + .333\left(1 - \frac{\text{bore, ins}}{100}\right)$$

These correspond with average practice. The addition of 100 lbs to the pres is made in order to allow for water-ram. Column B gives thicknesses by formula (1), taking coefficient of safety = 8 (thus making safe tensile strain = 2250 lbs per square inch) and adding three-tenths of an inch to each thickness given by the formula:

Head in feet	50		100		200		300		500		1000

Rem. The valves of water-pipes must be closed slowly, and the necessity for this precaution increases with their diams. Otherwise the sudden arresting of the momentum of the running water will create a great pressure against the pipes in all directions, and throughout their entire length behind the gate, even if it be many miles, thus endangering their bursting at any point. Hence stop gates are shut by screws.

Art. 18. Buoyancy. When a body is placed in a liquid, whether it float or sink, it evidently displaces a bulk of the liquid equal to the bulk of the immersed portion of the body; and the body, in both cases and at any depth, and in any position whatever, is buoyed up by the liquid with a force equal to the weight of the liquid so displaced. Thus, if we immerse entirely in water a piece of cork, *c*, *c*, Fig 26, or any body of less specific gravity than water, the cork will, by its weight, or force of gravity, tend to descend still deeper; but the upward buoyant force of the water, being greater than the downward force of gravity of the cork, will compel the latter to rise. In this case, the cork receives a total downward pressure equal to the weight of the vertical column of water above it, shown by the vertical lines in vessel 1; and a total upward pressure equal to the weight of the column shown in vessel 2. The difference between these two columns is evidently (from the figs) equal to the bulk of the cork itself; therefore the difference between their weights or pressures (or, in other words, the buoyancy of the water) is equal to the weight or pressure of the water which would have occupied the place of the cork; or, in other words, of the water which is displaced by the cork. This *difference*, or buoyancy, will plainly be very nearly the same at any depth whatever of *entire* immersion. It increases slightly with the depth, owing to increase in the density of the water; but, on the other hand it is diminished by compression of the cork. Now the cork, if left to itself, will continue to rise until a portion of it reaches above the surface, as in vessel 3. The downward pressing column then ceases to exist; and the cork is pressed downward only by its own weight. But, as it now remains stationary, the upward pressure of the water must be equal to the weight of the cork. But the upward pressure of the water arises only from the shaded column shown in vessel 3: and this column is (as in the case of total immersion) equal to the bulk of water displaced. Therefore, *in all cases*, the buoyancy is equal to the weight of water displaced; and when the body is in equilibrium, whether at or below water level, the buoyancy, or the weight of water displaced, is also equal to the weight of the body itself.

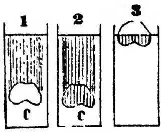

Fig. 26.

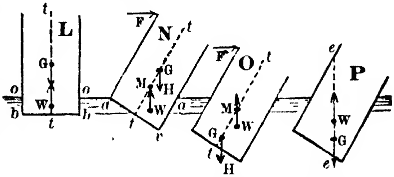
If the body be of a substance **heavier than water**, its weight is greater than the buoyancy of the displaced water, and the body therefore sinks, with a force equal to the difference between the two. Thus, a cubic foot of cast iron weighs 450 lbs., and a cubic foot of water 62.5 lbs., so that the iron sinks with a force of 450 — 62.5 = 387.5 lbs.

The same principle applies to **other fluids.** Thus, light bodies, such as smoke, a balloon, etc., in air, all tend, like a cork in water, to fall; but the air, being heavier, crowds them out of the lower positions which they tend to assume, and pushes them upward.

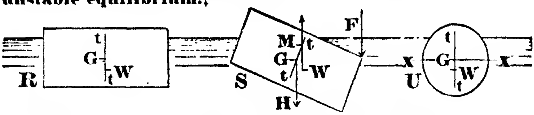
Although a pound of lead and a pound of feathers, weighed in the air, balance each other, yet in a vacuum the feathers will outweigh the lead, by as much as the air displaced by them outweighs that displaced by the lead.

The downwd force of grav may be regarded as concentrated at the cen of grav G of a floating body. The upwd pres, or buoyancy,† of the water may similarly be regarded as acting at the cen of gr W of the displaced water.* W is also called the **center of pressure,** or **of buoyancy,** of the water; and a vert line drawn through it is called the **axis,** or **vertical, of buoyancy,** or **of flotation.** Ordinarily,‡ W shifts its position with every change in that of the body Thus in L it is at the cen of gr of the rectangle *o o b b*; and in N at that of the triangle *a a r*

When a floating body, L, P or R, is at rest, and undisturbed by any third force, as F, it is said to be in **equilibrium,** and G and W are then in the same vert line *t t* Figs L and R, or *e e* Fig P; which line is called the **axis,** or **vertical, of equilibrium.**



When a third force,§ as F, in N and O, causes the line, joining G and W, to lean, as in Figs N, O and S, then if a vert line be drawn upwd from the cen W of buoy, the point M where said line cuts said axis, is called the **metacenter** of the body.‖ G and W are then no longer in the same vert line;‡ and the two opp and vert forces, grav and buoy, acting upon those points respectively, form a "couple" and, when the third force F is removed, they no longer hold the body in equilib, but cause it to rotate If (as in Figs O and S) the positions of G and W are then such that the metacenter M is *above* the cen of gr G, this rotation will tend to *restore the body to its former position*, and the body is said to have been (before the application of the third force F) in **stable equilibrium.**¶ But if (as in N) M is *below* G the direction of rotation is such as to *upset* the body, by causing it to *depart further from its former position*, and the body is said to have been in **unstable equilibrium.**‡



The tendency or moment in ft lbs of a floating body either to upset or to right itself, is,

= the wt of the body (or the equal upwd pres of the water) in lbs × the hor dist between W M and G H, Figs N, O and S, in ft.

The third force F may of course be so great as to overpower the tendency of the body to right itself. Thus, a ship may upset in a hurricane, although judiciously loaded and ballasted for ordinary winds. A hor section of a body at water-line is called its **plane of flotation.**

---

* **The body is in fact acted upon by other forces,** such as the hor pressures of the water against its immersed portions but as all of these in any one given direction are balanced by equal ones in the opposite direction, they have no effect upon the forces G and W It is also acted upon by the air, which presses it downwards with a force of 14 75 lbs per sq inch, but this is balanced by an equal pres of the surrounding air upon the surface of the water

† **This buoyancy is made up** of the parallel upward pressures of the innumerable vert filaments of the displaced water as shown by Fig 26, and the **axis of flotation** is their resultant, as in the case of parallel forces.

‡ The shape of a body (as that of a sphere or cylinder U) may be such that the position of its cen of buoy W, relatively to that of its cen of gr G, is not changed by the rotation of the body about a given axis (as any axis of the sphere or the *longitudinal* axis of the cyl), but remains constantly in the same vert line with G, so that the body, in rotating, remains in equilib Such a body is said to be in **indifferent equilibrium** about said axis. But if a cyl U be made to rotate about its *transverse* axis *x x*, it plainly comes under the remarks on Figs R and S, and may (before rotating) be in either stable or unstable equilib about that axis according to the way in which its wt is distributed.

‖ This metacenter shifts its position on the line *t t* according to the inclination of the latter.

§ **Uneven loading,** instead of a third force, may cause a vessel at rest to lean as at P; and yet the vessel so leaning may be in equilib, for its axis *e e* of equilib may be vert, although not coinciding with the **axis of symmetry** of the vessel, as it does at *t t* in L.

¶ In *floating* bodies, this may sometimes (as in Figs R and S) be the case even when the cen of buoy W (*not the metacenter*) is *below* the cen of gr G; because, when the body is forced to lean, W moves to another point in it, and this point may be such as to bring M above G. W is always below G in bodies of uniform density, floating at rest, if any part of the body is above water. When such bodies are entirely submerged, W and G coincide.

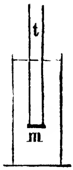


Fig 27

Art. 19. A body lighter than water, if placed at the bottom of a vessel containing water, will not rise unless the water can get under it, to buoy it, or press it upward, as the air presses a balloon or smoke upward. Thus, if one side of a block of light wood, *perfectly* flat and smooth be placed upon the similarly flat and smooth bottom of a vessel, and held there until the vessel is filled with water, the downward pres will keep it in its place, until water insinuates itself beneath through the pores of the wood. But if the wood be smoothly varnished, to exclude water from its pores, it will remain at the bottom.

On the other hand, a piece of metal may be prevented from sinking in water, by subjecting it to a sufficient *upward* pres only, while the downward pres is excluded. Thus, if the bottom of an open glass tube, *t*, Fig 27, and a plate of iron *m*, be made smooth enough to be water tight when placed as in the fig, and if in this position they be placed in a vessel of water to a depth greater than about 8 times the thickness of the iron, the upward pres of the water will hold the iron in its place, and prevent its sinking; because it is pressed upward by a column of water heavier than both the column of air, and its own weight, which press it downward. On this principle iron ships float.

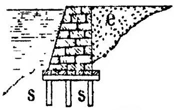

Fig 28

Rem 1. **A retaining-wall, as in Fig 28, founded on piles,** may be strong enough to resist the pres of the earth *e* behind it, in case water does not find its way underneath; and yet may be overthrown if it does; or even if the earth *s s* around the heads of the piles becomes saturated with water so as to form a fluid mud. In either case, the upward pres of the water against the bottom of the wall will virtually reduce the wt of all such parts as are below the water surf, to the extent of 62½ lbs per cub ft; or nearly one-half of the ordinary wt of rubble masonry in mortar.

Rem. 2. Although the piles under a wall, as in Fig 28, may be abundantly sufficient to sustain the wt of the wall; and the wall equally strong *in itself* to resist the pres of the backing *e*; yet if the soil *s s* around the piles be soft, both they and the wall may be pushed outward, and the latter overthrown by the pres of the backing *e*. From this cause the wing-walls of bridges, when built on piles in very soft soil, are frequently bulged outward and disfigured. In such cases, the piling, and the wooden platform on top of it, should extend over the whole space between the walls; or else some other remedy be applied.

Art. 20. Draught of vessels. Since a *floating* body displaces a wt of liquid equal to the wt of the body, we may determine the wt of a vessel and its cargo, by ascertaining how many cub ft of water they displace. The cub ft, mult by 62½, will give the reqd wt in lbs. Suppose, for instance, a flat boat, with vert sides, 60 ft long, 15 ft wide, and drawing unloaded 6 ins, or .5 of a ft. In this case it displaces 60 × 15 × .5 = 450 cub ft of water, which weighs 450 × 62½ = 28125 lbs, which consequently is the wt of the boat also. If the cargo then be put in, and found to sink the boat 2 ft *more*, we have for the wt of water displaced by the cargo alone, 60 × 15 × 2 × 62½ = 112500 lbs; which is also the wt of the cargo. So also, knowing beforehand the wt of the boat and cargo, and the dimensions of the boat, we can find what the draught will be. Thus, if the wt as before be 140625 lbs, and the boat 60 × 15, we have 60 × 15 × 62½ = 56250, and $\frac{140625}{56250} = 2.5$ ft the required draught. In vessels of more complex shapes, as in ordinary sailing vessels, the calculation of the amount of displacement becomes more tedious; but the principle remains the same.

HYDRAULICS.

Flow of Water through Pipes.

Much of the theory of hydraulics is still matter of dispute. This, and the unavoidable imperfections of actual work, render it advisable to use liberal safety factors in applying hydraulic formulas. Even new pipes are liable to tuberculations, which materially diminish the flow, and these sometimes greatly increase under the action of chemicals in the water. Air in the pipes also diminishes the flow.

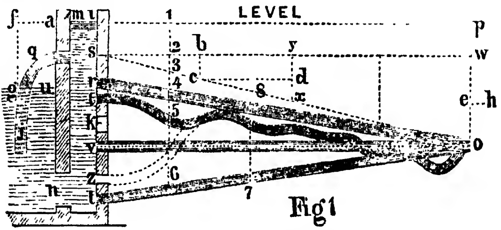

Fig 1

The term **HEAD** or **TOTAL HEAD** of water, as applied to the flowage of water through canals, pipes, or openings in reservoirs, &c, means the *vert* dist *i v* or *p o*, Fig 1, from the level surf, *m i*, of the water in the reservoir, or source of supply, to the center (or more properly to the cen of grav) *o*, of the orifice (whether the end of a pipe, *r o*, *t o*, *v o*, *z o*, *l o*; or any other kind of opening) through which the disch takes place freely, *into the air*; or the vert dist *a u*, or *f g*, from the same surf, *m i*, to the level *surf*, *g u*, of the water in the lower reservoir, when the disch takes place *under water*. Thus, in the case of disch *into the air*, the vert dist *i v* or *p o*, is the total head for either of the pipes *r o*, *t o*, *v o*, *z o*, or *l o*; and *i k* is the head for the orifice, *k*, in the side of the reservoir. And for disch *under water*, *a u*, or *f g*, is the head for either the pipe *j*, or the opening *n*; without any regard whatever to their depths below the surf of the lower water, which, according to the older authorities, do not at all affect their disch.

A portion of a pipe may have a head greater than the total head of the entire pipe. Thus the point 6 in the pipe *l o*, has a head 6 1; while the entire pipe has only the head *p o*.

Both in theory and in practice it is immaterial as regards the vel, and the quantity of water discharged, whether the pipe is inclined downward, as *r o*, Fig 1; or hor, as *v o*; or inclined upward, as *l o*: provided the total head *p o*, and also the length of the pipe, remain unchanged. If one pipe is longer than another, its sides will evidently present more friction against the water, and thus diminish the vel and the quantity of disch. The inclined pipes, *r o*, *l o*, being of course a little longer than the hor one *v o*, will therefore each disch a trifle less water, but if the hor one were extended slightly beyond *o*, so as to give it the same length as the others, then each of the three would disch the same quantity in the same time.

Art. 1 *a*. Divisions of the Total Head. In any pipe, as *s o*, *r o*, *t o*, *v o*, *z o*, or *l o*, Fig 1, the total head has three distinct duties to perform; 1st, to overcome the resistance to *entry* at *s*, *r*, *t*, *v*, *z*, or *l*; 2d, to overcome the resistances *within* the pipe; and, 3d, to give to the water, entering the pipe, the uniform *velocity* with which it actually flows

For convenience, we regard the total head as divided into three portions, corresponding to these duties; namely, 1st, the *entry* head; 2d, the *resistance*, or *friction*, head; and, 3d, the *velocity* head

Art. 1 *b*. The **velocity head** is the height through which a body must fall, in vacuo, to acquire the vel with which the water actually flows into the pipe. It is therefore = $\frac{v^2}{2g}$, in which v is the vel in ft per sec; and g is the acceleration of gravity, or 32 2

Art. 1 *c*. Experiment shows that, with the usual sharp-edged entry, the **entry head** is, near enough for practice, = half the vel head. If the entry is shaped like Fig 7, scarcely any entry head will be required But, in pipes longer than about 1000 diameters, the entry head bears so slight a proportion to the total head, that this advantage is of but little importance. It becomes more apparent in shorter pipes.

Art. 1 *d*. In Fig 1 we will assume that for any of the pipes, *i s* represents the sum of the vel and entry heads. Then the remainder *s v*, or *w o*, of the total head, is the **friction head**; or the head which is just sufficient to *balance* the friction and other resistances *within* the pipe; and, since the *entry* head balances the resistance at the *entrance* to the pipe, the *velocity* head has only to give velocity to the water in the vessel, causing it to enter

the pipe as rapidly as it flows through it, and thus keeping the pipe supplied. If, by shortening the pipe, or by smoothing its inner surf, we diminish the total friction, then a less friction head will be required, but the vel will, at the same time, be increased, and this will require a greater vel head, and entry head, so that the three together make up the total head, as before. Since the *friction is* equal to the force or head reqd to overcome it, it also is represented by *w o*.

Art. 1 e. The friction head may as in *v o*, *z o*, and *l o*, Fig 1, be all *above* the entrance to the pipe, and therefore *outside* of the pipe; or, as in a pipe laid from *s* to *o*, it may be all *below* the entrance, and *within* the pipe; or as in *r o* and *t o*, it may be partly above, and partly below, the entrance, and therefore partly within, and partly without, the pipe. The vel and disch, *after the pipe is filled*, are not affected by this difference in position of the entry end; but the *pressures* in the pipe, and the vels *while the water is filling an empty pipe*, are affected by it.

Art. 1 f. But it is necessary that the entry end of the pipe should be placed so far below the surf *m i*, that there shall be left, above the cen of grav of the entry end, at least a head, *i s*, sufficient to perform the duties of the entry and vel heads. If the entry end of any of the pipes be raised above *s*, a portion of the *vel* head will be *in* the pipe. In other words, the head *in* the pipe will be more than sufficient to overcome the resistances in the pipe; and the surplus will act as vel head, and will give greater vel to the water *in* the pipe. The *reduced* head thus left above the entry end will plainly be insufficient to maintain the supply for the *greater* vel, and the pipe will run only partly full.

In ordinary cases of pipes of considerable length, the sum of the entry and vel heads theoretically required, is but a small portion of the total head, and rarely exceeds a foot. Indeed, in a pipe of considerable diameter, the upper half of its cross section at the entry end may often be more than enough to provide sufficient entry and vel heads above the cen of grav of said cross section; so that the top of the entry end might, so far as these considerations alone are concerned, project above the surf of the water in the reservoir. But the end of the pipe should in practice always be entirely below the surf; otherwise air and floating impurities will be drawn into it, and cause obstructions. Moreover, the water surf of reservoirs is always liable to considerable changes of height; and the entry end of the pipe must be placed at such a depth that the water can flow into it with sufficient vel when at its *lowest* stages. As before stated, this will cause no diminution or increase of disch.

Art. 1 g. To find the friction head reqd for any part of a pipe; knowing the fric head reqd for the whole pipe. Since the friction, in a pipe of uniform diam, is (other things being equal) in proportion to its length; and since *w o*, Fig 1, represents the total friction, or reqd friction head, we have

Total length of the pipe : Length of the given portion : : *w o* : The friction head reqd for that portion

Or, having drawn *w o* by scale, *s w* hor, and *s o*;

Total length of the pipe : Length of the given portion : : *s o* : A dist, as *s c*, to be laid off from *s* on *s o*.

Or : : *s w* : A dist, as *s b*, to be laid off from *s* on *s w*

Then a vert line, as *b c*, drawn from *b* or *c*, and joining *s w* and *s o*, gives by scale the friction head reqd.

Art. 1 h. If the pipe is straight, as *r o*, *v o*, *l o*, the friction in any part *beginning at the reservoir*, as *l 6* in the pipe *l o*, may be found at once by drawing a line 6 1 vert upward from the axis of the pipe at 6. The line 2 8 will then give the friction in *l 6*. It also gives the friction in *r 4*, or in that part of *v o* which lies between *v* and the dotted line 1 6. It must be remembered that all the pipes in Fig 1 are supposed to be of the same actual length. They would thus end at different points *o*, and strictly a separate diagram must be drawn for each pipe. In a part of the pipe *not* beginning at the reservoir, as in *r o*, *v o*, or *l o*, between points vertically under *c* and *x*, the amount of friction is given by the line *d x*, for it is plainly $= y\,x - b\,c$

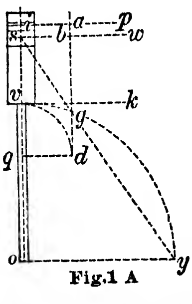

Fig.1 A

Art. 1 j. If the pipe is vert, as *v o*, Fig 1 A, let *v s* (on its axis *l o*) represent, as before, the sum of the vel and entry heads. From *s*, *v*, and *o*, respectively draw hor lines *s w*, *v k*, and *o y*, making *o y* = *v o*. Draw the oblique line *s y*. Then, to find the friction in any part, as *v q*, beginning at the reservoir, from *q* lay off *q d* hor, and equal to *v q*, and draw the vert line *a d*, crossing *s y* at *g*. Then *b g* will give the friction in *v q*.

Art. 1 k. If the pipe is curved, and if the curvature is uniformly distributed along its length, or so slight that it may be neglected; the friction heads reqd for the several portions of the pipe, may be found in the same way as for straight pipes, as in Art 1 H. Otherwise they must be found by proportion, as in Art 1 G.

Art. 1 l. While water is filling an empty pipe, the excess of the total head above the requirements of friction, &c, gives to the water a **greater vel** than it has after the pipe is filled; but this gradually decreases as the advancing water encounters the friction along the increased lengths of pipe filled; and finally becomes least when the water fills the whole length, and begins to flow from the disch end. *o*. But if only the vel and entry heads are left above the entry end, as in a pipe laid from *s* to *o*, there will plainly be no such excess of total head, and, consequently, no such change of vel during the filling of the pipe.

Art. 1 *m-r*.* Relation between discharge, area, velocity and pressure. In Fig 1 *B-D*, where the pipe, *b F*, running full, receives water from an unlimited reservoir, *R*, at *b*, and discharges through an orifice, *F*; the volume of water, passing any given cross section of *b F*, in a given time, is constant and equal to the rate of discharge at *F*. Thus;—if the rate of discharge, at *F*, be *Q* cubic feet per second, then *Q* cubic feet will pass each cross section of the pipe, *b F*, per second.

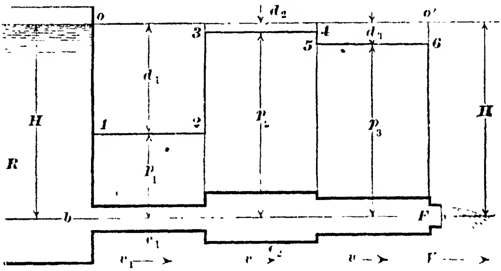

Fig. 1 B-D.

Let a = the area of cross section, and V = the velocity, of the stream issuing through the short pipe beyond *F*. V is called the velocity of efflux.

Let A_1, A_2, etc., be the different areas of cross section of *b F*, and let v_1, v_2, etc., be the velocities at those cross sections respectively. Then $Q = a\,V = A_1\,v_1 = A_2\,v_2$, etc.; or $V = \frac{Q}{a}$, $v_1 = \frac{Q}{A_1}$, $v_2 = \frac{Q}{A_2}$, etc. In other words, the velocities are inversely as the areas of cross section. Also, $a = \frac{Q}{V}$, $A_1 = \frac{Q}{v_1}$, $A_2 = \frac{Q}{v_2}$, etc.

The losses of pressure, due to the velocities, respectively, are $d_1 = \frac{v_1^2}{2g}$, $d_2 = \frac{v_2^2}{2g}$, etc.; as represented by the ordinates between the line $o\,o'$, of static pressure, and the diagram, *o* 1 2 3 4 5 6 *F*, of actual pressures. The difference, due to velocity, between the pres heads at any two points, as c_1 and c_2, where the velocities are v_1 and v_2 respectively, is $p_2 - p_1 = d_1 - d_2 = \frac{v_1^2}{2g} - \frac{v_2^2}{2g} = \frac{v_1^2 - v_2^2}{2g}$.*

The remaining pressure head, p_1, p_2, etc., at any point, is = static head in reservoir — velocity head at the point, = $H - d_1$, $H - d_2$, etc.

The loss of pressure head, at *F*, is $(6\ F) = p_3 = H - d_3$, and the pressure drops to zero, i.e., to the atmospheric pressure.

Art. 1 *s*. Open piezometers. If the lower ends of vertical or inclined tubes, open at both ends, be inserted into a pipe, *b F*, Fig. 1 *B D*, as at c_1, c_2, etc., the water surface, in these tubes, will stand at heights, p_1, p_2, etc., corresponding to the pressure heads at the points where the tubes are inserted. Such tubes are called open piezometers. In order that the water level may be observed, they are of glass, at least in those portions where that level is likely to be found. An obstruction, in the pipe, between c_2 and *F*, would *raise* the level in a piezometer at c_2; while an obstruction between *b* and c_2 would *lower* it.

*In Art. 1 *m-r*, for simplicity, we neglect all resistances, including those due to the abrupt enlargements and contractions of the pipe.

Art. 1 t. If we imagine any pipe, full of water, to be supplied with a number of piezometers, then a line, joining the tops of the columns of water in the several piezometers, is called the **hydraulic grade line.**

Art. 1 u. In a straight tube of uniform diam throughout, as *r o*, *r o*, or *l o*, Fig 1, running full and discharging freely into the air, the hyd grade line is a straight line drawn from its disch end *o* to a point *s* immediately over the entry end of the pipe, and at a depth below the surf equal to the sum of the vel and entry heads.

If the orifice at *o* be contracted, the hyd grade line must be drawn from *s* to some point, as *e*, immediately over *o*, and depending, for its height, upon the amount of contraction at *o*. But in this case the point *s* will also be higher than before, because the vel in the pipe is reduced by the contraction; and the sum *i s* of the vel and entry heads will be less.

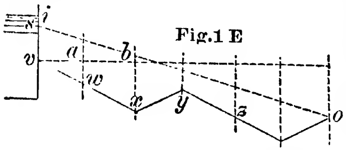

Fig.1 E

If the disch at *o* is under water, the effect upon the position of the grade line will be the same as that of a contraction of the orifice at *o*. The point *e* will be on the surf of the lower water, and immediately over *o*.

Art. 1 v. If the pipe, of uniform diam, (whether discharging freely or through a contracted opening at *o*, whether into the air or under water), **is bent or curved,** the hyd grade line will still be straight, **provided** the resistances are equal in each equal division of the *hor* length of the pipe, as in Fig 1 E, where equal divisions *v w*, *w x*, &c, of the *total* length, correspond with equal divisions *i a*, *a b*, &c, of the *hor* length.

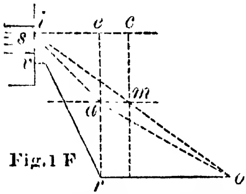

Fig.1 F

But in Fig 1 F, the hyd grade line will take the shape *s a o*. For if, in accordance with Art 1 G, we divide *s o* into two equal parts, *s m*, *m o*, corresponding with the two equal parts *v r*, *r o* of the length of the pipe, we obtain *m c* = *a e* for the head consumed in the resistances in *v r*, leaving only *r a* for the pres head at *r*.

Art 1 w. In a very large vessel, the total head upon any point at the level of the entrance *l* to a pipe *l o o'* Fig 1 G, is represented by *i l*, as already explained but of this total head a portion, as *i s*, is required to act as velocity head and entry head for the entrance at *l*, leaving only *s l* as the pressure head upon a point in the *pipe*, immediately to the right of *l*. Thus while the pressure, in pounds per square inch, in the *vessel* at *l*, is

$$p = i\,l \times 0.434\,,$$

that in the *pipe* at *l* is

$$p = s\,l \times 0.434.$$

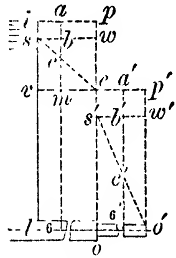

Fig.1 G

But now a portion, as *s r*, of *s l*, is expended in *l o* in balancing or "overcoming" the resistances throughout that portion of the pipe, and in doing this work, it gradually diminishes from *s r* (at *l*) to nothing (at *o*) as indicated by the dotted line *s e*. Thus, at the point 6, a portion *b e* has already been expended in overcoming the resistances in the pipe between *l* and 6, leaving *e* 6 as the pressure head at 6, of which *e m* must still be expended against resistances in the wide pipe between 6 and *o*, leaving *m* 6 = *r l* = *e o* as the pressure head for a point just to the left of the contraction at *o*. The pressure in *l o* is thus gradually diminished from *s l* (at *l*) to *e o* = *r l* (at *o*).

Now a portion *e s'* of *e o* is required to act as velocity and entry head for the entrance *o* to the narrower portion *o o'* of the pipe; because we need at *o* not only an additional *entry* head to overcome the resistance due to the square shoulder formed by the contraction, but also an additional *velocity* head to give the increase of velocity which must take place as the water passes from the wide pipe *l o* to the narrower one *o o'*; for, so long as a pipe runs *full* and the discharge remains constant, the *velocity* in each part of the pipe must be *inversely as the area* of cross section of that part; because in each second the same quantity of water passes each point; and this constant quantity is = area × velocity. Hence, as the area diminishes, the velocity increases.

There remains, therefore, *s' o* as the pressure head upon a point in the narrow part just to the right of *o*; and this in turn gradually diminishes to nothing at

the end o' of the pipe, as indicated by the dotted line $s\,o'$, being all expended in overcoming the resistances in $o\,o'$. We thus have, for the hydraulic gradient in Fig 1 G, the broken line $i\,s\,e\,s'\,o'$.

When the pressure is thus diminished by overcoming resistances, or by accelerating velocity, the diminution is called **loss of head.** Thus we say that $i\,s$ is *lost* at the entrance l, $s\,i$ as friction head in $l\,o$, $e\,s'$ at the contraction o, and $s'\,o$ as friction head in $o\,o'$,

At o', *all* the available head, $i\,l$, has been used up. The water flowing out at o', therefore exerts no lateral pressure, so that the stream flows out in parallel lines, and its capacity for forward pressure is due entirely to its kinetic energy (energy of motion) and to the pressure of the air upon the surface in the reservoir at i; but this last is of course balanced by the air pressure from without against the opening o'. Where a great reduction of cross sectional area in a pipe is followed (down-stream) by a re-enlargement, the increase of velocity may (under certain circumstances) consume not only the entire head of *water*, but also a portion or all of the *atmospheric* pressure on the surface in the reservoir, thus causing a partial or complete vacuum at the constriction. See the Venturi Meter.

The syphon, or siphon If one leg $a\,b$ of a bent tube or pipe $a\,b\,c$, Fig M, of any diam, filled with water, and with both its ends stopped, be placed in a reservoir of water, as in the fig, and if the stoppers be then removed, the water in the reservoir will begin to flow out at c, and will continue to do so until its level is reduced to t, which is the same as that of the *highest* end c of the pipe or syphon. The flow will then stop. The parts $a\,b$ and $b\,c$ are called the legs of the syphon, b being its highest point, and this is correct so far as relates to it merely as a piece of tube, but considering it purely with regard to its character as a hydraulic machine, the part $t\,a$ below the level of the highest end c, may be entirely neglected, for the water in the reservoir will not be drawn down below the level of the highest end, whether that be the inner or the outer one. Therefore, if the disch end be above the water in the reservoir, as, for instance, at w, no flow will take place. The *vert* height $b\,o$, from the highest part of the syphon, to the lowest level t, to which the reservoir is to be drawn down, must not, theoretically, exceed about 33 or 34 ft, or that at which the pres of the air will sustain a column of water. Practically it must be less, to allow for the friction of the flowing water, and for air which forces its way in. And still less at places far above sea level; for at such the reduced weight of the atmospheric column will not balance so great a height of water. In order readily to understand, or at any time to recall the principle on which the syphon acts, bear in mind that we may theoretically consider the end of the inner leg to be not actually immersed *below* the water surf, but only to be kept precisely *at* it, as the surf descends while the water is flowing out, but may regard the vert dist $b\,o$ as the length of the outer leg; and a varying dist, which at first is $b\,s$, and finally $b\,o$ (as the surf of the reservoir descends) as the length of the inner leg; and that the flow continues only while *this* outer leg is longer than *this* inner one The books are wrong in saying that the outer leg $b\,c$ *must* be longer than the inner one $b\,a$, in order that the water may run at all. The principle then is simply this: that both these legs $b\,c$, and $b\,i$, being first filled with water, (the part $i\,a$ being considered at first as a portion of the *reservoir*, and not of the syphon,) it follows that when the stoppers are removed from the ends c and a, the air presses equally against these ends; but the great vert head of water $b\,o$ in the outer leg $b\,c$, presses against the air at c, with more force than the small head of water $b\,s$ in the inner leg $b\,i$, does against the air at a or i.* Consequently, the water in $b\,c$ will tend to fall out more rapidly than that in $b\,i$; and as it commences to fall, would produce a vacuum at b, were it not that the pres of the air against the other end a or i, forces the water up $i\,b$, to supply the place of that which flows out at c. In this manner the flow continues until the surf of the water in the reservoir descends to t, on the same level as c. The pressures of the vert heads $b\,o$, $b\,o$, in the two legs $b\,c$, $b\,t$, being then equal, it ceases.

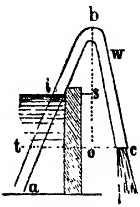

Fig. M.

The syphon principle may be employed for draining ponds into lower ground at a considerable dist, even though an elevation of several feet (in practice perhaps not *exceeding* about 28 ft above the level to which the pond is to be reduced) may intervene. In such a case an **escape** must be provided at the summit (or summits, if there are more than one) of the bends, for the disch of free air, which will inevitably enter, and soon stop the flow, unless this precaution be taken. The air-valve will not answer for this, because as soon as the valve v opens, the syphon becomes in effect two separate tubes open at top; and the water will fall in both. An orifice at the escape will be needed for filling the syphon at the start; and to prevent the water thus introduced, from running out, stopcocks must be provided at the ends, and kept closed until the filling is completed.

The greatest pains must be taken to make all the joints perfectly air-tight.

The motive power or head which causes the flow in a syphon, is the vert dist $s\,o$, from the surf of the reservoir, to the disch end c; or in other words, it is the diff, $s\,o$, between the theoretical lengths $b\,s$ and $b\,o$, of the two legs. Con-

* Said pressure of the air is of course not exerted directly at a or i; but is transmitted to a through the water in the vessel; and thence upward to i through the water in the syphon.

sequently, the farther *c* is below *s* the more rapid will be the flow; and it is plain that as the surf gradually sinks below *s*, the less rapid will the flow become. Having this head, the entire length *abc* of the syphon, and its diam, all in ft, the disch may be found approximately by either of the rules given in Art 2 for straight pipes. These rules give 55½ galls per min, instead of the 43½ galls actually dischd by Col Crozet's syphon, with a head of 20 ft. See below.

In a true syphon, *a g n y o* Fig 1½, *free from air* inside, and *running full*, **the total head** *p o* is measured vertically from the surface *m i* in the reservoir to the center of gravity of the outlet *o*, as in Fig 1, **the hydraulic gradient** (with the restriction named in Art 1 *i*) is, as before, a straight line *s r o* drawn from the foot *s* of the combined entry and velocity heads to the end *o*, and the velocity and discharge are the same as they would be if all parts of the pipe were brought below *s r o*. But see cautions 1 and 2, below.

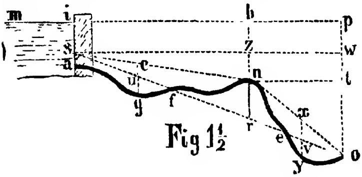

Fig 1½

The pressure at any point, *g*, *n* or *y*, is then given by a vertical line, *g u*, *n r* or *y v*, drawn from the point in question to *s r o* but for points, as *n*, situated *above s r o*, this pressure is *negative* or *inward*, while at points where *s r o* and the pipe are at the same level, as at *f* and *e*, there is neither pressure nor vacuum

Caution 1. But if the water be admitted to the empty pipe at *a*, while the end *o* is open, the pipe will not form a true syphon The part *a g n* will then run full, and will have *s c n* as its hydraulic gradient, but upon reaching at *n*, a portion *n o* of the pipe with a much steeper grade, the water will run off, in *n o*, with a velocity greater than that with which it arrives from *a n*. Hence the stream in *n o* will have a less area of cross section than in *a n*, and therefore cannot fill *n o*, but will run off in it as in an open gutter.

Caution 2. The tendency to vacuum at points above *s r o* causes an accumulation, at *n*, of particles of **air** that have been carried into the syphon by the water or have found their way in through imperfect joints, etc.; and these bring about a condition approaching that described in Caution 1; for their expansive force, by reducing the negative pressure or vacuum *n r* at *n*, diminishes the total head *h r* of the part *a g n*, while, by practically reducing the cross-section of the syphon at *n*, they require that a portion of the remaining head be used at *n*, as entry head to overcome the resistance caused by the contraction, and as velocity head to give the increase of velocity needed for passing the narrowed section at *n* Now since the friction head required for the part *a g n* remains about the same, the velocity head in the reservoir is considerably diminished, and the water arrives at *n* too slowly to keep *n o* filled. The accumulation of air at *n* thus retards the flow and disturbs the distribution of the pressures, so that these are no longer correctly indicated by vertical lines drawn to *s r o*.

At Blue Ridge Tunnel, Virginia, Col. C. Crozet constructed a drainage syphon 1792 ft long of cast iron faucet pipes 3 ins bore, 9 ft long. Its summit was 9 ft above the surface of the water to be drained; and its discharge end was 20 ft below said surface, thus giving it a head of 20 ft. At the summit 570 ft from the inlet, was an ordinary cast iron **air-vessel** with a chamber 3 ft high and 15 ins inner diam. In the stem connecting it with the syphon was a **cut-off stop-cock**; and at its top was an opening 6 ins diam, closed by an air tight screw lid. At each end of the syphon was a stopcock. **To start the flow** these end cocks are closed, and the entire syphon and air-vessel are filled with water through the opening at top of air-vessel This opening is then closed airtight, and the two end cocks afterwards opened; the cut-off cock remaining open. The flow then begins, and **theoretically** it should continue without diminution, except so far as the head diminishes by the lowering of the surface level of the pond. **But in practice** with very long syphons this is not the case, for air begins at once to disengage itself from the water, and to travel up the syphon to the summit, where it enters the air-vessel, and rising to the top of the chamber gradually drives out the water. If this is allowed to continue the air would first fill the entire chamber, and then the summit of the syphon itself, where it would act as a wad completely stopping the flow. **The water-level in the air chamber** can be detected by the sound made by tapping against the outside with a hammer

To prevent this stoppage, the cut-off at the foot of the chamber is closed before the water is all driven out; and the lid on top being removed the chamber is refilled with water, the lid replaced, and the cut-off again opened. The flow in the meantime continues uninterrupted, but still gradually diminishing notwithstanding the refilling of the chamber; and after a number of refillings it will cease altogether, and the whole operation must then be repeated by filling the whole syphon and air chamber with water as at the start.

At Col. Crozet's syphon at first owing to the porosity of the joint-caulking, which was nothing but oakum and pitch, air entered the pipes so rapidly as to drive all the water from the chamber and thus require it to be refilled every 5 or 10 minutes; but still in two hours the syphon would run dry. The joints were then thoroughly recaulked with lead, and protected by a covering of white and red lead made into a putty with Japan varnish and boiled linseed oil. But even then the chamber had to be refilled with water about every two hours; and after six hours the syphon ran dry, and the whole had to be refilled. In this way it continued to work.

Care in making the joints air-tight, and an outside and inside coating of the pipes and air-vessel with coal pitch varnish are important precautions.

Art. 2. Approximate formulæ for the velocity of water in straight, smooth, cylindrical iron pipes, as *r o*, *i o*, *l o*, Fig. 1. Having the total head *p o*, and the length and diameter of the pipe.

$$\left.\begin{array}{c}\textbf{Approx}\\ \textbf{mean vel}\\ \text{in ft per sec}\end{array}\right\} = \begin{array}{c}\text{coefficient}\\ \textbf{m}\\ \text{as below}\end{array} \times \sqrt{\frac{\text{diam in ft} \times \text{total head in ft}}{\text{total length in ft} + 54 \text{ diams in ft}}}$$

Table of coefficients "m".

Diam of pipe, feet	inches	**m**	**Diam** of pipe, feet	inches	**m**
0.1	1 2	23	1.5	18	53
0 2	2 4	30	2.0	24	57
0 3	3.6	34	2 5	30	60
0.4	4 8	37	3.0	36	62
0.5	6.0	39	3.5	42	64
0.6	7 2	42	4.0	48	66
0 7	8.4	44	5.0	60	68
0 8	9.6	46	6 0	72	70
0 9	10.8	47	7.0	84	72
1.0	12 0	48	10.0	120	77

For heads not less than 4 feet per mile, this formula gives results practically corresponding with those by Kutter's formula (p. 523) with coefficient n of roughness = 0.012. But slight differences, as to roughness, etc, may cause considerable variations of velocity, especially in small pipes; for, in such pipes, a given roughness of surface bears a greater proportion to the whole area of surface than in a pipe of large diameter. Extreme accuracy is not to be expected in such matters.

As in a river the velocity half way across it, and at the surface, is usually greater than at the bottom and sides, so in a pipe the velocity is greater at the center of its cross section than at its circumf. The **mean velocity** referred to in our rules is an assumed uniform one which would give the *same discharge* that the actual ununiform one does.

Hence

$$\begin{array}{c}\textbf{Discharge}\\ \text{in cub ft per sec}\end{array} = \begin{array}{c}\textbf{Mean velocity}\\ \text{in ft per sec}\end{array} \times \begin{array}{c}\textbf{Area of cross section}\\ \text{of pipe in sq ft.}\end{array}$$

1 cubic foot = 7.48052 U.S. gallons
1 U. S. gallon = .13368 cubic foot = 231 cubic inches.

* For intermediate diameters, etc, take intermediate coefficients from the table by simple proportion.

In the case of long pipes with low heads, the sum of the velocity and entry heads is frequently so small that it may be neglected. Where this is the case, or where their amount can be approximately ascertained, **Kutter's formula**, although designed for open channels, may be used. This formula is the joint production of two eminent Swiss engineers, E. Ganguillet and W. R. Kutter, but for convenience it is usually called by the name of the latter.*

It is, properly speaking, a formula for finding the coefficient c in the well known formula,

$$\textbf{Mean velocity} = c\sqrt{\text{mean radius} \times \text{slope}}$$

$$= c\sqrt{\frac{\text{diameter}}{4} \times \text{slope}}$$

According to Kutter,

For English measure. **For metric measure.**

$$\mathbf{c} = \frac{41.6 + \frac{.00281}{\text{slope}} + \frac{1.811}{n}}{1 + \frac{\left(41.6 + \frac{.00281}{\text{slope}}\right)n}{\sqrt{\text{mean rad in } feet}}} = \frac{23 + \frac{.00155}{\text{slope}} + \frac{1}{n}}{1 + \frac{\left(23 + \frac{.00155}{\text{slope}}\right)n}{\sqrt{\text{mean rad in } metres}}}$$

See also **tables of c**, pp 566 etc.

The mean radius is the quotient, in feet or in metres, obtained by dividing the area of wet cross section, in square feet or in square metres, by the wet perimeter (see below) in feet or in metres. In pipes running full, or exactly half full, and in semicircular open channels running full, it is equal to one-fourth of the inner diameter.

The wet perimeter is the sum, *a b c o* Fig C, p 528, of the lengths, *a b*, *b c*, *c o*, in feet or in metres, found by measuring (at right angles to the length of the channel) such parts of its sides and bottom as are in contact with the water. In pipes running full, it is of course equal to the inner circumference.

For the slope, we have

$$\textbf{Slope} = \frac{\textit{friction} \text{ head } w\ o \text{ Fig 1,}}{\text{length of pipe.}}$$

In open channels, this becomes

$$\textbf{slope} = \frac{\text{fall of water surface in any portion of the length of the channel}}{\text{length of that portion}}$$

$$= \text{fall of water surface per unit of length of channel}$$

$$= \text{sine of the angle formed between the sloping surface and the horizon.}$$

The number indicating the slope in any given case is plainly the same for English, metric and all other measures.

"n" is a "coefficient of roughness" of wet perimeter, and of course depends chiefly upon the character of the inner surface of the pipe as related to its size, a given diff in roughness resulting in a greater diff of n in large than in small pipes. For iron pipes in good order and from 1 inch to 4 feet diameter, n may be taken at from 0.010 to 0.012; the lower figures being used where the pipe is in exceptionally good condition. See pp. 564–5.

*See "Flow of Water," translated from Ganguillet and Kutter, by Rudolph Hering and John C. Trautwine, Jr., New York, John Wiley & Sons, 1889. $4.00.

Curves and bends do not greatly affect the discharge, so long as the total heads, and total actual lengths of the pipes remain the same; provided the tops of all the curves be kept below the hydraulic grade line; and provision be made for the escape of air accumulating at the tops of the curves.

Relation between area, velocity, and discharge.

Let q = rate of discharge (as in cubic feet per second),
v = mean velocity (as in feet per second),
a = area of cross section (as in square feet).

Then: $q = a\,v;\quad v = \dfrac{q}{a};\quad a = \dfrac{q}{v}$.

Relation of discharge to diameter* and slope. If we assume velocity = $c\sqrt{\text{mean radius} \times \text{slope}}$, or $v = c\sqrt{r\,s}$ (page 523); and if the pipe be of circular cross section, we have, for the rate, Q, of discharge through a pipe of diameter, d, and area, A, of cross section, running full:—

$$Q = A\,v = \frac{\pi\,d^2}{4} \cdot c\,\frac{d^{1/2}}{2}\,s^{1/2} = \frac{c\,\pi\,d^{5/2}\,s^{1/2}}{8};$$

or: Q is proportional to the $^5/_2$ power (square root of fifth power) of the diameter, and to the ½ power (square root) of the slope. For tables of fifth powers, and of square roots of fifth powers, see pp 67–69

Effect of resistances.

The pressure head of running water, upon any point in a pipe between the orifice and the reservoir, is:

$$= \left\{\begin{array}{l}\text{the total}\\ \text{head on}\\ \text{that point}\end{array}\right\} \text{minus} \left\{\begin{array}{l}\text{the head}\\ \text{due to the}\\ \text{vel at}\\ \text{that point}\end{array} + \begin{array}{c}\text{the}\\ \text{entry}\\ \text{head}\end{array} + \begin{array}{l}\text{the head consumed}\\ \text{in overcoming re-}\\ \text{sistances in the pipe}\\ \text{between the reservoir}\\ \text{and the point.}\end{array}\right\}$$

Thus, at the point 6, in the pipe, $l\,o$, Fig 1, the pressure head is $h = (3\,6) = (1\,6) - [(1\,2) + (2\,3)]$; where $(1\,2) = i\,s$ = the sum of the velocity and entry heads At 4, in the pipe $r\,o$, $h = (3\,4) = (1\,4) - [(1\,2) + (2\,3)]$.

In Fig 1, let the straight line, $s\,o$, represent the actual length of the pipe, whether straight, bent or curved, etc.; and $s\,v$ the sum of the resistances (supposed to be uniformly distributed) within the pipe Then, the angle, $s\,o\,v$, is called the hydraulic gradient, and sine $s\,o\,v = s\,v \div s\,o$

In the vertical pipe, $v\,o$, Fig 1 A, the pressure, at q, is = $g\,d$

---

* Diameter = 4 × mean radius, or $d = 4\,r$ (p 523).

TABLE OF WEIGHT OF WATER CONTAINED IN ONE FOOT LENGTH OF PIPES OF DIFFERENT BORES. *

(Original.)

Water at maximum density, 62.425 lbs per cubic foot = 1 gram per cubic centimeter, corresponding to a temperature of 4° Centigrade = 39.2° Fahrenheit.

Weight = 0.340475558 × square of bore in inches.

The weight of water in a given length (as one foot) of any pipe or other circular cylinder **is in proportion to the square of the bore** or inner diameter. Hence the weight of water in 1 foot length of any cylinder of other diameter than those in the table can be found by multiplying that for a 1 inch pipe, 0.340475558, by the square of the inner diameter of the given cylinder in inches. Thus, for a cylinder 120 inches diameter: diameter^2 = 120^2 = 14400, and weight of water in 1 foot depth = 0.340475558 × 14400 = 4902.848 lbs. Or, weight for 120 ins. diam. = 100 × weight for 12 ins. diam. = 100 × 49.02848 = 4902.848 lbs. Similarly, $\left(\frac{7}{16}\right)^2 = \frac{49}{256}$ = 0.191406, and 0.340475558 × 0.191406 = 0.065169 lb. = weight in 1 foot of $\frac{7}{16}$ inch pipe. Here, also, $\frac{7}{16}$ = *half* of $\frac{7}{8}$; hence, weight for $\frac{7}{16}$ inch = one-*fourth* of weight for $\frac{7}{8}$ inch = one-fourth of 0.260677 = 0.065169.

Weight of one square inch of water 1 foot high, at 62.425 lbs. per cubic foot = 62.425 ÷ 144 = 0.433507 lb.

* Actual. See nominal and actual diameters, foot note, p 526.

Pipes*. Areas; Contents; Square roots of Diameters. Original.
D = diameter* in inches; **d** = diameter in feet.
A = cross section area in sq ft, = cub ft in 1 ft length.
For **d**, see p 221. Thus; let D = 17¾ ins = 12 ins + 5¾ ins.
Then (p 221) d = 1 ft + 0.4792 ft = 1.4792 ft. Or, square $\sqrt{d}$.

Caution.** In the tables, pp 525 and 526, the diameters or bores are the *actual* ones, as mesured in inches. Wrought iron and steel steam, gas and water pipes are commonly designated by fictitious or **"nominal"** diameters, which are mere arbitrary names. * In the smaller sizes especially, the discrepancies are serious. Thus, the pipe whose "nominal" inner diam is *one eighth* inch has an ***actual inner diam of *full quarter* inch. See p 1164.

Art. 3. Theory of flow in long pipes and channels.

Resistance to flow. When one solid body moves over another, most of its particles retain practically their original relative places; but when water flows, as in a pipe or channel, the roughnesses and irregularities, which exist in even the smoothest surfaces, disturb the current, the several particles describing spiral or other paths not parallel to the general direction of flow. Resistance to flow is believed to be due to such disturbances, rather than to friction proper, as we understand it in solids See p 407, and ¶ 194, p. 415

In the absence of complete knowledge respecting the nature of these disturbances, we are forced to rely upon experiment in determining the manner and extent of their influence upon the flow.

Mean velocity: rate of discharge. Figs A, B. In a pipe or

Fig. A.

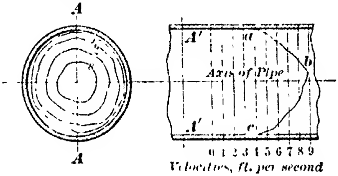

Fig. B.

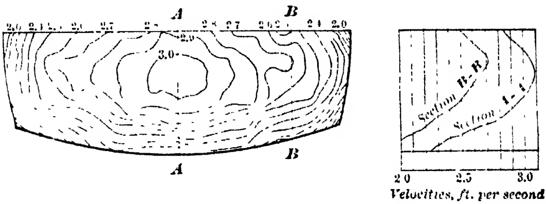

channel, owing to the disturbing influence of contact with the sides, the particles of water move in tortuous paths The **mean velocity**, through the entire cross section at any point, is the quotient obtained by dividing the rate of discharge by the area of cross section **At any given point** in a cross section, **the velocity**, as recorded by any form of current meter, is the component, parallel to the axis of the pipe, of the actual velocity of the particles passing that point. We deal, at present, only with cases of **"steady flow,"** *i. e*, where the velocity, at each point, remains constant.

The velocities, as measured at different points in the cross section of a pipe or channel, are generally least near the sides of pipes, and near the sides and bottoms of channels

In Fig A, the longitudinal section shows one of many series of velocity measurements by Messrs Williams, Hubbell and Fenkell* on a cast iron pipe, 16 ins diameter The measurements were made, by means of the Pitot tube, on a vertical diameter, such as A A in the cross section The horizontal distances of the several points in the curve, *a b c*, from the vertical line, 0, represent, by the scale below the figure, the velocities at the several points in the diameter. In the cross section, the several curved lines are lines of equal vel.

Fig B shows the results of measurements of velocities in a cross section of the Sudbury Conduit, Mass.,† 9 feet wide, 3 feet deep. In the longitudinal section, the velocities, at different depths on the lines A A and B B of the cross section, are (approximately) indicated as in Fig A. In the cross section, the several curved lines are lines of equal velocity. The innermost one corresponds to a velocity of 3 ft. per second; the next, to 2.9 ft per second, and so on.

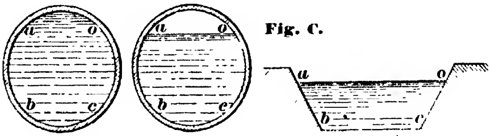
Formulas for discharge, q, and mean velocity, v, in a given length, L, of a straight **pipe or channel** of uniform wet cross section. Referring to Fig. C, let

Fig. C.



$L =$ the given length ;
$p =$ the wet perimeter, $a\,b\,c\,o$;
$A = L\,p =$ the area of the wetted surface ;
$a =$ the cross section area of the liquid stream ;
$r = \frac{a}{p} =$ the mean radius of its cross section ;
$d =$ diam of pipe ; *
$q =$ the rate of discharge
$=$ volume passing a given cross section, a, in unit time ;
$v = \frac{q}{a} =$ the mean velocity ;
$h_v = \frac{v^2}{2\,g} =$ the velocity head ;
$m\ c,\ f,\ F =$ resistance factors, as explained below and at top of p 530.
$h_f =$ the resistance (or "friction") head in the length, L ;
$s = \frac{h_f}{L} =$ the slope.

It is generally held that the resistances to flow are directly proportional to A and to some power (usually taken as v^2 †) of v, and inversely proportional to a. Or:

friction head, $h_f = m\,\frac{A\,v^2}{a} = m\,\frac{L\,p\,v^2}{a} = m\,\frac{L\,v^2}{r}$; and $m = h_f\,\frac{r}{L\,v^2} = \frac{r\,s}{v^2}$;

whence

$v^2 = h_f\,\frac{a}{m\,L\,p} = \frac{r\,s}{m}$; and **velocity**, $v = \sqrt{\frac{r\,s}{m}} = \sqrt{\frac{1}{m}}\,\sqrt{r}\,\sqrt{s}$.

Let $c = \sqrt{\frac{1}{m}}$; $m = \frac{1}{c^2}$. Then we have the **Chezy formula**:—

velocity, $v = c\,\sqrt{r\,s} = c\,\sqrt{r}\,\sqrt{s} = c\,r^{0.5}\,s^{0.5}$.

For "Kutter's formula," giving values of c, see p 523, and pp 564 to 574. For tables of c, by Kutter's formula, see pp. 565 to 570

The resistance, or roughness factor, such as m, f, F or c, above, or c_H in the Hazen formula below, must be selected by judgment, or determined, as by Kutter's formula, pp. 523, 564, &c, according to the known or assumed condition of the wetted surface.

Weisbach's formula for friction head, $h_f = m\,L\,v^2/r$, in feet and seconds. ($g = 32.2$ ft per sec per sec.)

Friction head $h_f = [0.0144 + (0.017 / \sqrt{v})]\,L\,v^2 / 2\,g\,d$.

This formula is based upon early experiments with small pipes. For pipes above say 20″ diam, modern practice shows greater friction heads for given vels. Compare Fig D, pp 529 a, 529 b.

* In full semi-circular channels, and in full or half-full pipes, $d = 4\,r$.
† See "Exponential" formulas, p 529.

Art. 3 a. "Exponential" formulas.* Careful study of experiments upon large and small pipes and channels, under varying conditions, indicates that the mean velocity depends, not upon the *square* roots, or 0.5 powers, of r and of s, but generally upon somewhat higher powers; and that the inaccuracy, involved in taking 0.5 for the exponents in the Chezy formula, accounts for the wide variation of the Chezy c, with r and with s, for a given condition of inner surface of pipe or channel.

Gardner S. Williams and Allen Hazen adopt the formula:—

$$v = c_H \, r^{0.63} \, s^{0.54} \; 0.001^{-0.04};$$

the last factor, $0.001^{-0.04} = 0.001^{0.5 - 0.54} = 1000^{0.04} = 1.32$, being inserted in order to make their values of c_H, in ordinary cases, more nearly equal with the values of c in the Chezy formula.† To facilitate the application of their formula, they furnish a "hydraulic slide rule," by means of which mean vels, and the losses of head due to different vels in different pipes and channels, may be readily found. Their "Hydraulic Tables,"‡ have been calculated in this way.

Fig D, pp 529 *a* and *b*. **Diagram of discharges, velocities and head-losses,** in pipes and conduits, by Williams-Hazen formula, as above.

Example. Given a 24" cast iron pipe, 2000 ft long, to carry 2,000,000 gals/24 hrs, after 40 yrs use carrying av soft unfilterd water. Reqd, the vel and the head-loss.

Velocity. Starting at D, on lower scale (2,000,000 gals/24 hrs) follow the vert line until it meets, at E, the inclined *dotted* line for 24" pipe. The hor line, thru E, gives the reqd vel, 1 ft/sec.

Head-loss. On small diagram A (either page) find intersection, B, of 40-yr age line with curvd line for 24" pipe, giving $c_H = 80$. Find intersection, C, of line for $c_H = 80$ with curvd line of main diagram for 24" pipe. Follow the *direction* of the *solid* inclined lines from C to the intersection, F, with the hor line for vel = 1 ft/sec. From F, follow the vert line to G, on the lower scale, giving the reqd head-loss, 0.4 ft/1000 ft = 0.8 ft in the given length of 2000 ft. (And vice versa.)

In diagram A, the curv markt ∞ applies to cases where the diam is not reduced by service, and to large pipes in general.

Approximate values of c_H:

Pipes and conduits, running full;

3 to 60 inches diameter;		**Over 60 inches diameter;**	
Cast iron;	c_H	Iron, masonry, etc.	c_H
Very best, new, carefully coated and laid	140	Extremely smooth and straight	140
Good, new	130 to 120	Very smooth	130
In fair condition	100	Good masonry	120
Tuberculated	80 to 40	Brick sewers	100
Riveted steel;		Rough	90
New	110	Very rough	80
		Tile sewers:	
Ten years old	100	4 to 36 ins diam	110

Open channels. (For a given character of surface, and given wet perimeter, c_H, like c in the Chezy formula, is max for max area of cross section.)

Sudbury conduit, 8 ft wide,	c_H	Rough masonry, 4 ft wide,	c_H
1 to 5 ft deep	130 to 140	1 ft deep	65 to 75
Smooth wood	110 to 140	Gravel	50 to 80
Unplaned plank	100 to 120	Earth, very rough	65 to 75
Good Masonry	80 to 120	With mud, grass and weeds	35 to 70

* Formulas in which the exponents are other than 0.5 have been called "exponential," in order to distinguish them from those where the exponent is 0.5; but these last are, of course, no less "exponential."

† The values of c, given by the Kutter formula and in our tables, pp. 566, etc., contain the correction necessitated by the fact that the velocity is not strictly proportionate to the square roots of r and of s.

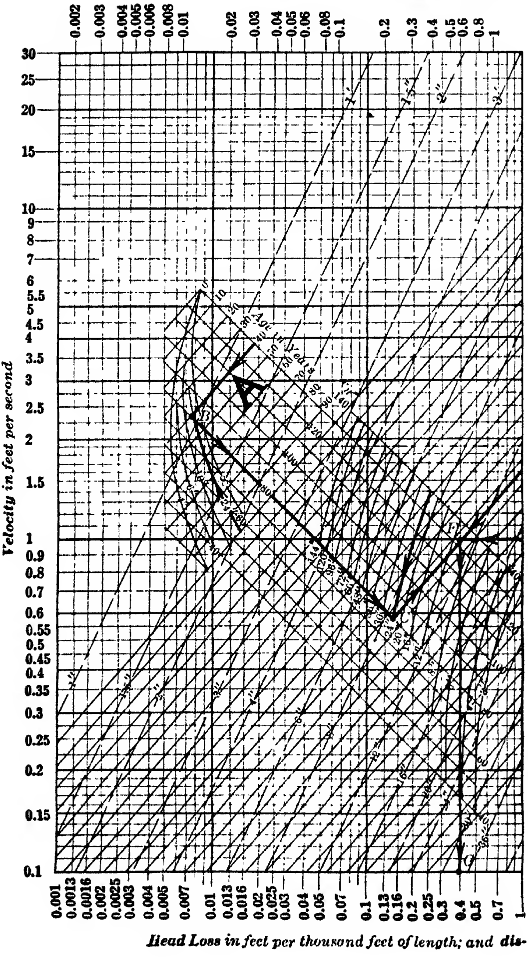
Fig. D. *Discharges, Velocities and Head Losses in Pipes and Con-*

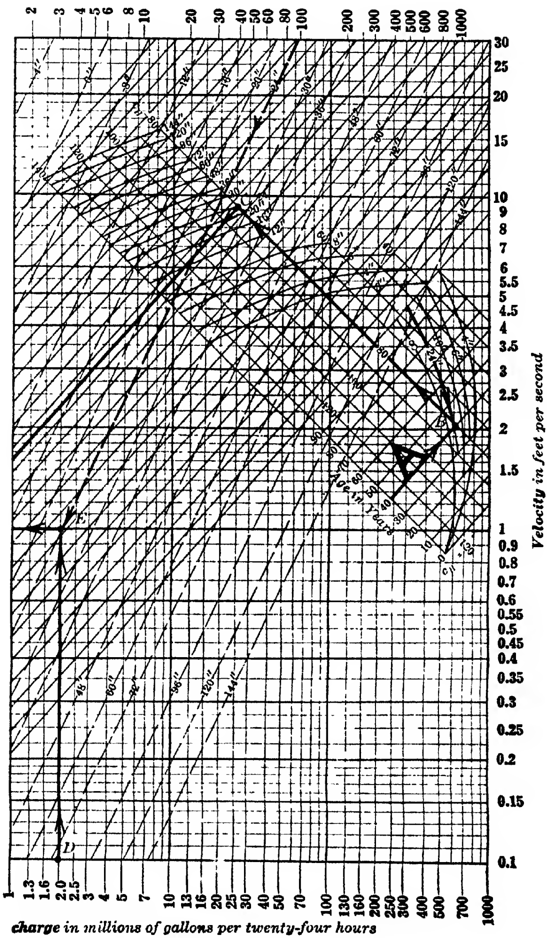
Discharge in Cub-



Head Loss in feet per thousand feet of length; and dis-

duits, by Williams-Hazen Formula; $V = C_H\, r^{0.63}\, s^{0.54}\, 0.001^{-0.04}$

ic feet per second



charge in millions of gallons per twenty-four hours

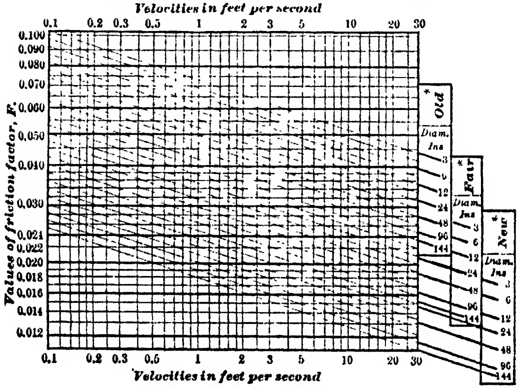
Friction factor. Let

$$f = 2\,g\,m = \frac{2\,g}{c^2} = 2\,g\,.\,h_f\,\frac{r}{\mathrm{L}\,v^2} = 2\,g\,.\,\frac{r\,s}{v^2}; \qquad \mathrm{F} = 4\,f^{*} = 2\,g\,.\,\frac{d\,s}{v^2}.$$

F or f is usually called **the friction factor.** It expresses the relation (determined by the condition of the wetted surface of the pipe or channel) between velocity and dimensions, on the one hand, and the resistance to flow on the other. Thus

$$h_f = f\,.\,\frac{\mathrm{L}}{r}\,.\,\frac{v^2}{2\,g}\dagger = 4\,f\,.\,\frac{\mathrm{L}}{4\,r}\,.\,\frac{v^2}{2\,g} = \mathrm{F}\,.\,\frac{\mathrm{L}}{d}\,.\,\frac{v^2}{2\,g}.\ddagger{}^{*}$$

Values of friction factor, *F*, for iron pipe. See page 531.



Example of use of diagram. Given a 6 inch pipe, in fair condition. In the column, on the right, headed "Fair," find diam, 6 ins. Following to the left the direction of the short inclined line, preferably by means of a rule or straight-edge of paper, we find that it coincides nearly with one of the inclined lines which cross the diagram. By means of the intersections of this line with the others, we find that, for the pipe in question, a velocity of 5 ft per sec corresponds approximately with F = 0.035; 0 5 ft per sec, F = 0.048, etc., etc.

* "Old," "fair," and "new" correspond approximately with values of Kutter's "n" (p. 564) as follows:

Diameter..	3 inch		6 inch		12 inch		60 inch		120 inch	
Slope, in ft per 1000 ft	10.0	1.0	10 0	1.0	10 00	0 4	10 00	0 05	1 000	0.025
	n	n	n	n	n	n	n	n	n	n
Old	0.012	0.013	0 014	0 014	0 015	0.016	0.018	0.020	0.019	0.021
Fair.........	0 011	0.011	0.012	0 012	0.013	0 014	0 014	0.015	0.015	0.017
New	0.010	0.010	0 010	0.010	0.011	0.012	0.012	0.013	0.013	0.014

* This applies where $d = 4\,r$. In pipes running full or half-full, and in semicircular channels running full, $d = 4\,r$.

† See Mechanics of Engineering, by I P Church, 1890, p. 714, Eq. (8).

‡ See Hydraulics, by Mansfield Merriman, 1905, p. 209. Eq. (86).

Art. 4. To find the discharge, q, through a long compound pipe, or pipe of varying diameter, Fig. 1 H.

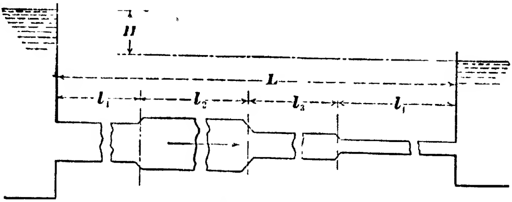


Fig. 1 H.

Let

l_1, l_2, l_3, etc. = the lengths of the several portions of the pipe;
d_1, d_2, d_3, etc = the corresponding diameters;
v_1, v_2, v_3, etc. = the corresponding velocities;
F_1, F_2, F_3, etc = the corresponding values of the resistance or "friction" factor. See p. 530.
$L = l_1 + l_2 + l_3 +$ etc. = the total length of the pipe;
H = the total head (p. 516);
q = rate of discharge $= \frac{1}{4} \pi d_1^2 v_1 = \frac{1}{4} \pi d_2^2 v_2 =$ etc.

In a long pipe, the velocity and entry heads are usually negligible, relatively to the friction head. Neglecting them, we have

H = total head = friction head.

In each portion of the pipe, the resistance, and the corresponding "friction" head, h_f, are believed to be proportional directly to the length, l, of such portion, and to the velocity head, $\frac{v^2}{2g}$, and inversely to the diameter, d; or

$$h_f = F \cdot \frac{l}{d} \cdot \frac{v^2}{2g}.$$

Hence,

$$H = F_1 \cdot \frac{l_1}{d_1} \cdot \frac{v_1^2}{2g} + F_2 \cdot \frac{l_2}{d_2} \cdot \frac{v_2^2}{2g} + F_3 \cdot \frac{l_3}{d_3} \cdot \frac{v_3^2}{2g} + \text{etc.};$$

and, since $v_1 = \frac{4q}{\pi d_1^2}$, $v_2 = \frac{4q}{\pi d_2^2}$, etc.,

we have, also,

$$2gH = F_1 \cdot \frac{l_1}{d_1} \cdot \frac{16 q^2}{\pi^2 d_1^4} + F_2 \cdot \frac{l_2}{d_2} \cdot \frac{16 q^2}{\pi^2 d_2^4} + \text{etc.}$$

$$= \frac{16 q^2}{\pi^2} \left(F_1 \cdot \frac{l_1}{d_1^5} + F_2 \cdot \frac{l_2}{d_2^5} + \text{etc.} \right)$$

whence

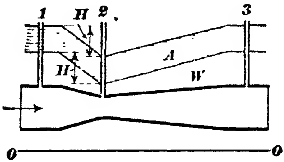
$$q = \frac{\pi}{4} \sqrt{\frac{2gH}{F_1 \frac{l_1}{d_1^5} + F_2 \frac{l_2}{d_2^5} + \text{etc.}}}$$

Art. 4 a.* **The Venturi Meter** is designed for the measurement of the flow of liquids in pipes of large dimensions, running full.

The meter proper, patented by Clemens Herschel, consists essentially of a mere constriction in the area of cross-section of the pipe, with openings in the pipe opposite its normal and its constricted diameters, for measuring, by piezometers or pressure-gauges, the pressures at those points, while **the register** is an elaborate mechanism, provided with clock-work and dials.

Theory.† Let Figs. 1 to 3 represent a Venturi meter tube, with three piezometers in place, viz: No 1, over the tube up-stream from the constriction; No 2, over the constriction itself, and No 3, over the tube down-stream from the constriction. Let the unshaded area *W* in Figs 1 to 3, represent the depths at which the water stands above any assumed horizontal datum plane *O O*, and let the shaded area *A* represent the uniform pressure of the atmosphere, which, for convenience, we may suppose to be converted into some liquid of the specific gravity of water, but distinguishable, by its appearance, from the water.

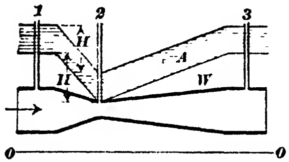
Fig 1



The vertical distance, between the upper boundary of this latter area and any given point in the tube, represents the combined pressure of air and water at such point.

The velocities in the meter tube at any instant, are of necessity inversely proportional to the areas of cross section, and, as the heads corresponding to the several velocities are proportional to the squares of those velocities, the remaining or pressure heads must vary also, the smallest or lowest pressure head standing over the throat, where the velocity is greatest.

Fig 2.



The increase of velocity, acquired by the fluid in passing from section 1 to section 2, is again given up in passing from section 2 to section 3, and, in the case of a perfect fluid the pressure lost between sections 1 and 2 would be perfectly restored in passing from section 2 to section 3. In practice, a small total loss occurs. This loss is greater with high than with low velocities.

For a given head in piezometer No 1 and given diameter of pipe at section 1, the expenditure of head in velocity between sections 1 and 2 increases as the area of the throat is diminished and as the throat velocity is thereby increased.‡ In Fig. 2 is shown the case where all of the water head above the top of the throat is required to maintain the velocity through the throat.

In Figs 1 and 2 the head, *H*, expended in the increase of velocity between sections 1 and 2 is represented by the difference in level between the tops of the two water columns 1 and 2, or between the tops of the two corresponding air columns. In Fig. 2 this difference is equal to the *total* vertical height of the water column at section 1 above the top of the throat at section 2.

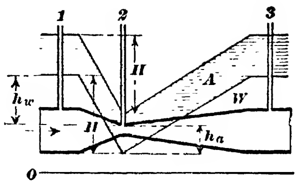
* Abridged from a description prepared by the writer as Chairman of a Committee of the Franklin Institute. *Journal of the Franklin Institute,* February, 1899.

† The Venturi meter, apart from its merits as a measuring device, embodies important hydraulic principles. Hence its theory is here stated more fully than would otherwise be necessary.

‡ In a given Venturi tube the pressure and velocity at the throat may be varied also by modifying those at sectons 1 and 3, as by regulating the openings of the valves of influx to and of efflux from the meter tube, by changing the total head on the system, etc.

If now (Fig. 3) the throat section be still further reduced (the other conditions remaining as before) the throat velocity will thereby be still further increased, for the *total* pressure available for increase of velocity between sections 1 and 2 consists not merely in the depth of *water* above the tube, but also in the *atmospheric pressure*, represented by the shaded area *A* above the water *W*.

Fig. 3.

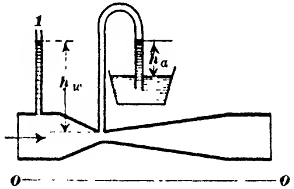


In Fig 3 all the water has disappeared from piezometer 2, and even a portion of the liquid representing the air has also disappeared, leaving only a portion of the latter to represent such pressure as now remains in the throat In other words, the pressure within the throat is now less than the atmospheric pressure

In Fig 3, the loss of head, due to increase of velocity between sections 1 and 2, is $H = h_w + h_a$ - the entire available head of water, h_w, plus a portion, h_a, of the atmospheric pressure The latter portion, h_a, is frequently called "the vacuum"

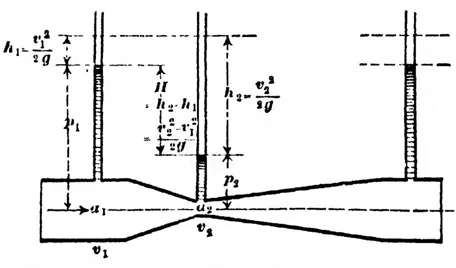
The top of the water column having now disappeared below the top of the throat, it is no longer feasible to ascertain the loss of head by taking the difference between the levels of the water surfaces in piezometers 1 and 2. The degree of "vacuum" may be found, as shown in Fig 4, by using, in place of the piezometers, a glass tube bent over and led *downward* into an open vessel containing water or mercury. The height to which the water (or the mercury, converted into feet of water) rises in this tube, shows the extent of the vacuum, or the portion, h_a, of the air pressure which has been called into service in producing the high velocity through the throat. By adding this to h_w, we obtain, as above, the total loss of head H between sections 1 and 2

Fig. 4.



When the reduction of area at the throat has proceeded so far that the entire available pressure of water and air at section 1 is required, in order to maintain the corresponding velocity through the throat (*i e.*, when the line representing the upper surface of the air falls to the level of the top of the throat),

Fig. 5



no further increase of throat velocity can be secured (with a given total head over section 1) by still further narrowing the throat. If the throat is further narrowed, the velocity through it will remain the same; and, the rate of discharge being thus diminished, the velocity through section 1 will be necessarily reduced. In other words, throttling begins

Let v_1 be the velocity in section 1, above the throat, and v_2 the "throat velocity," or velocity in the throat or section 2.

Neglecting resistances, Fig. 5, the velocity head at section 1, measured from an assumed datum represented by the upper horizontal lines, is

$$h_1 = \frac{v_1^2}{2g},$$

and that at section 2 is

$$h_2 = \frac{v_2^2}{2g}.$$

Neglecting resistances to flow, the loss of head, between sections 1 and 2, or "the head on the Venturi," is equal to the increase in the velocity head, or to the loss in pressure, between a_1, and a_2, or

$$H = h_2 - h_1 = \frac{v_2^2}{2g} - \frac{v_1^2}{2g} = \frac{v_2^2 - v_1^2}{2g} = p_1 - p_2{}^*$$

Hence, $$h_2 = \frac{v_2^2}{2g} = H + h_1$$

and **throat velocity** $= v_2 = \sqrt{2g\,(H + h_1)} = \sqrt{2g\left(H + \frac{v_1^2}{2g}\right)}.$

In other words, the velocity at the throat is that corresponding to the "head H on the Venturi," plus the head corresponding to the velocity of approach v_1 in section 1.

But, since the velocities are inversely as the areas of cross-section a_1 and a_2,

$$v_1 = \frac{a_2}{a_1} v_2, \qquad \text{and } v_1^2 = \frac{a_2^2}{a_1^2} v_2^2,$$

$$H = \frac{v_2^2 - v_1^2}{2g} = \frac{v_2^2 - \frac{a_2^2}{a_1^2} v_2^2}{2g} = \frac{\left(1 - \frac{a_2^2}{a_1^2}\right) v_2^2}{2g} = \frac{\frac{a_1^2 - a_2^2}{a_1^2} v_2^2}{2g},$$

$$v_2^2 = \frac{2g\,H a_1^2}{a_1^2 - a_2^2},$$

and **throat velocity** $= v_2 = \frac{a_1}{\sqrt{a_1^2 - a_2^2}} \sqrt{2g\,H}.$

The ratio $$\frac{a_2}{a_1},$$

between the area a_2 of cross-section at the throat, and that, a_1, at the upper end of the up-stream cone, is called the **throat ratio.** For a ratio of 1 : 9 we have

$$\frac{a_1}{\sqrt{a_1^2 - a_2^2}} = \frac{9}{\sqrt{9^2 - 1^2}} = \frac{9}{\sqrt{80}} = \sqrt{\frac{81}{80}} = 1.0062.$$

or $$v_2 = 1.0062\sqrt{2g\,H}.$$

The Venturi tube, for pipes not over 60 inches in diameter, is formed of several short sections of cast iron pipe, having the required taper, and fur-

---

* By Bernouilli's theorem, $p_1 + h_1 = p_2 + h_2$.

nished with flanges, by means of which the sections are bolted together to form the two truncated cones required.

In the smaller sizes, the shorter cone is generally in one section and the longer cone in two or more sections.

The throat section is generally made in a separate piece, and is either made of bronze or lined with that metal.

The ends of the Venturi tube are furnished with either bell, spigot, or flanged ends, according to the character of the pipe in which the tube is to be used.

For still larger streams, such as those in masonry conduits or riveted flumes, the Venturi tube may be made of wooden staves, sheet steel, cement concrete, brick or other suitable material, metal being used for the throat piece and where required by the pressure.

The throat piece is surrounded by an annular chamber called the **pressure chamber,** which communicates with the interior of the throat by means of several holes drilled radially through the walls of the latter at equal or nearly equal distances around the circumference.

A similar pressure chamber is provided at the larger end of the short cone for observing the pressure in the normal section up-stream from the throat; and, if it is desired to ascertain the final loss of head due to the passage of the water through the Venturi, a similar chamber must be provided at the larger end of the longer or down-stream cone.

In designating the size of the meter, the diameter of the pipe of which it forms a part is used, and not the throat diameter. Thus, a meter for use in a 6-inch pipe is called a 6-inch meter.

The register gives periodic registrations, usually every ten minutes, in which the head $H = h_2 - h_1$, existing at the instant of registry, is recorded in terms of the total discharge in cubic feet since the last registry and as an increase in the total number of cubic feet registered. In other words, the registry involves the assumption that the average velocity, during the period between two registrations, is equal to the velocity at the instant of the following registration.

The register may be placed at a considerable distance (not exceeding, say, 500 feet) from the Venturi tube. It must be placed at such a depth below the hydraulic grade line that the pressures existing in the Venturi tube shall at all times be transmitted to the register.

The pipe lines, connecting the Venturi with the register, must be covered, and a shelter from weather and frost must be provided for the register.

The size and cost of the register are independent of the size of the Venturi.

Behavior. From experiments by Mr. Herschel,* † ¶ by the Bureau of Water, Philadelphia,† and by others,† it appears that the Venturi meter may ordinarily be depended upon to give results within 3 per cent of the true discharge.

With a 48 inch Venturi, Mr Herschel ¶ found a total **loss of head,** due to the passage of the water through the Venturi tube, of about 10.6 per cent. of the head H on the Venturi. With two 54 inch Venturis, Professors Marx, Wing, and Hoskins § † found a loss of 14.9 per cent, part of which, no doubt, was due to the presence of a 42 inch gate valve in the down-stream cone. This last result would add about 1.12 feet to the head required in pumping 20,000,000 gallons daily through a 48 inch main and a Venturi having a throat ratio of 1 : 9.

The Venturi meter has been found to give perfectly satisfactory results in measuring the flow of brine and very hot water.

Venturi tubes are made with throat ratios ranging from 1 : 4½ (or 2 : 9) to 1 : 16. The former are adapted to high, and the latter to low velocities; for, where the velocity in the pipe is low, it is necessary to accelerate it greatly in the throat in order to obtain sufficient loss of pressure to secure reliable indications in the register. These cannot be obtained where the throat velocity is less than about 3 feet per second. With a throat ratio of 1 : 16, this would give a pipe velocity of $\frac{3}{16}$ foot per second. On the other hand, a meter with a high throat ratio, adapted to low velocities, would, with high velocities, exceed the upper limit of the register.

Owing to its unobstructed channel, free from moving parts, the Venturi meter is far less liable to clogging than the forms of meter in common use.

The **prices** of the principal sizes of the Venturi meter are as follows:—on board cars at Providence, R. I.

6 inch $600.00	24 inch $1,130.00	48 inch $3,060.00
12 inch 770 00	36 inch 1,680.00	60 inch 4,890 00

These prices include the register, which, in the smaller sizes, constitutes the principal item of cost. Discount, 1901, 10 per cent.

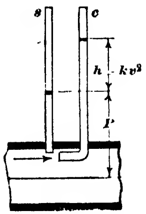
§ Trans. Am. Soc. Civil Engrs., Vol XL., Dec., 1898, pp. 471 etc.

Art. 4 b. The Ferris-Pitot meter, invented and patented by Mr Walter Ferris, of Philadelphia, is designed to measure the flow of liquids in pipes running full. It consists of a device for the registration of the results obtained by the Pitot tube, described on pages 561 and 562, and of special devices to prevent the clogging of the tubes and to permit their examination while in use.

In Fig. 6 let P represent the level at which the water stands in the straight Pitot tube, s. Then $h = kv^2$, or the difference in level between the columns in the two tubes, is the head (theoretically $= \frac{v^2}{2g}$) due to the velocity of the water in the pipe as it impinges against the open up-stream end of the bent tube, c. For a given velocity, v, this difference, h, is constant, and is independent of the pressure represented by P.

Fig. 6.



The Ferris register, like that of the Venturi meter, records the velocity (existing at the instant of registration) in terms of the total discharge since the last registry and as an increase in the total number of cubic feet registered. The registry thus involves the assumption that the average velocity, during the period between registrations, is equal to the velocity at the end of that period. In the Ferris meter the registration is made every two minutes.

Evidently the instrument measures the velocity at only one point in the cross-section of the pipe, and it may thus be used to determine successively the velocities at any number of such points, but the velocity at such a point may or may not be equal to the mean velocity in the entire cross-section. The instrument is therefore usually calibrated by reference to some accepted standard, and the coefficient or coefficients thus obtained are used in subsequent observations.

The recording mechanism is operated by a small hydraulic motor, driven by means of the flow of the water in the pipe itself. For this purpose a second pair of Pitot tubes, is inserted into the pipe, and the current, flowing through these tubes, drives the motor without loss of water, the water used for power being returned to the pipe. If the velocity in the pipe is less than 3 feet per second it must be increased by means of a "reducer."

Experiments made by Mr. Ferris and by the Bureau of Water, Philadelphia, indicate that the Ferris-Pitot meter will ordinarily register within 3 per cent of the true discharge.

In general, the size and cost of the registering apparatus are independent of the size of the pipe.

Art. 5. Resistance of curves and bends in water pipes.

Much uncertainty exists respecting these matters. **Weisbach's formula,*** for the resistance due to a circular curve, Figs. 2 and 3, is

$$h = C\,\frac{A}{180}\cdot\frac{v^2}{2\,g} = \left[0.131 + 1.847\left(\frac{r}{R}\right)^{\frac{7}{2}}\right]\frac{A}{180}\cdot\frac{v^2}{2\,g}\text{, where}$$

h = head in feet required to overcome resistance due to curve or bend,
C = experimental coefficient,
A = angle of deflection, in degrees,
v = mean velocity of flow in pipe, in feet per second,
g = acceleration of gravity = 32.2 ft per sec per sec,
$v^2/2\,g$ = head theoretically due to velocity v,
D = inside diameter of pipe, in feet,
r = inside radius of pipe, in feet,
R = radius of axis of curve, in feet.

If $r \div R$ =	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	**0.9**	**1.0**
then C =	0.131	0.138	0.158	0.206	0.294	0.440	0.661	0.977	**1.408**	**1.978**

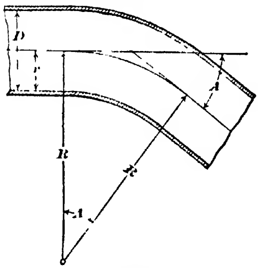


Fig. 2.

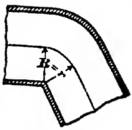

Fig. 3.

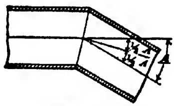

Fig. 4.
(See next page.)

According to this formula, the resistance due to curvature decreases rapidly as R increases from ½ D to 2 D; and but little further decrease occurs beyond R = 5 D; but, from very careful and elaborate experiments on city water mains, from 12 to 30 ins diameter, in Detroit, Mich.,† the investigators conclude that a line of pipe with a curve of *short* radius R (down to a limit of R = 2½ D) causes *less* resistance than does a line of equal length and equal total angle A, with a curve of longer radius R. Their results were approximately as follows, where

H = resistance due to a section of 80 diameters in length, with a curve of A = 90° at mid-length,
h = resistance in a tangent of length = 80 diameters.

If R ÷ D =	1	2	2.5	3	4	5	10	15	20	25
then H ÷ h =	1.35	1.14	1.13	1.14	1.18	1.24	1.50	1.66	1.80	1.93

They found also that the **loss of head,** due to a curve, occurs **not only in the curve itself,** but that head continues to be lost in the following tangent, for some distance **down stream** from the curve.

Their experiments led to the inference that even very **slight deflections, A,** in the line, **cause material losses of head,** and that care in securing a straight alignment is therefore highly advisable. For **bends,** see next page.

* Der Ingenieur, pp. 444, 445.
† Paper by Gardner S. Williams, Clarence W. Hubbell, and George H. Fenkell, Transactions, American Society of Civil Engineers, Vol. XLVII, April, 1902.

For abrupt angles, Fig. 4, Weisbach gives: Resistance, in feet of head =

$$h = c\,\frac{v^2}{2\,g} = (0.95 \sin^2 \tfrac{1}{2}\,A + 2.05 \sin^4 \tfrac{1}{2}\,A)\,\frac{v^2}{2\,g}$$

If $\frac{1}{2}$ A =	10°	20°	30°	40°	45°	50°	55°	60°	65°	70°
then c =	0.03	0.14	0.36	0.74	0.98	1.26	1.56	1.86	2.16	2.43

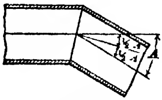

Fig. 4.

In addition to the resistance offered to flow, curves and bends involve additional labor and expense in manufacture and in laying; and vertical bends and curves lead to the formation of pockets of sediment at the feet of slopes, and of air cushions at their summits.

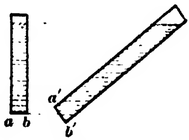

Fig. 5.

Art. 6. Although, in Fig. 5, the static pressures upon the equal bases, $a\,b$ and $a'\,b'$, of the two pipes are equal (see Hydrostatics, Art. 1); yet, in order to pump water through either pipe, at a given velocity, an *additional* force is required, in order to overcome resistances to flow, and these resistances and the additional force required in order to overcome them, will be greater in the longer than in the shorter pipe.

Art. 7. Flow through orifices. Theoretically the velocity, v, of a fluid, flowing through a small orifice in the side or bottom of a very large vessel, is equal to that acquired by a body falling freely in vacuo through a height equal to the head, h, or depth, measured vertically from the level surface of the fluid in the vessel, to the center of gravity of the orifice; or,

$$v = \sqrt{2\,g\,h} = \sqrt{64.4\,h} = 8.03\,\sqrt{h};$$

and

$$h = \frac{v^2}{2\,g} = \frac{v^2}{64.4} = 0.0155\,v^2.$$

This law applies equally to all fluids. Thus, theoretically, mercury, water, air, etc., all flow with equal velocities from a given orifice under a given head.

For deviations in practice from this theoretical law, see Art. 9, etc.

Art 8. Flow, into air, thru short tubes, Fig. 6. Length, L, = $n'\,i$ or $n\,e$, of tube, $\nless$ 2.5 to 3 times its *least* transverse dimension, d. Head, h, constant and > half hight of tube.

Let v = mean velocity thru tube;
g = acceleration of gravity
= 32.2 ft per sec per sec; ($\sqrt{2\,g} = 8$);
= 9.81 meters per sec per sec; ($\sqrt{2\,g} = 4.43$).
h = head, $n\,s$, from grav center of tube cross section to water surface;
L = length, $n'\,i$ or $n\,e$, of tube;
d = least transverse dimension of tube;
a = tube cross section area,
q = discharge rate thru tube;
c = an experimental coefficient.

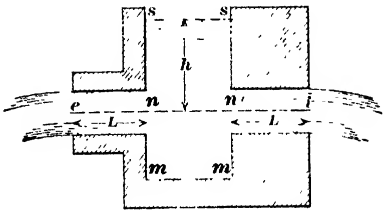

Fig. 6.

Then, if the flow fills the tube ("full flow" or "full bore"), we have.

$v = c\sqrt{2\,g\,h}$; $q = v\,a = c\,a\sqrt{2\,g\,h}$.

L/d	< 1.5	2.5 to 3	4	6	10	15	20	40	60	100
c, approx	0.61	0.81	0.80	0.76	0.74	0.71	0.69	0.62	0.57	0.48

If the outflowing stream fails to fill the tube cross section, the coeff, c, is greatly reduced. This may be obviated by temporarily closing the outlet from the tube, thus backing up the water and compelling it to fill the tube. Then, when the outlet is opened, the air pressure, on the outer end of the outflowing stream, may be expected to keep the stream in contact with the inner tube surface. The sides of the tube should be free from greasiness.

If $s\,m$ be a channel cross section, the vel and disch thru the short tube, $n'\,i$ or $n\,e$, are **not affected by the flow** of the water in the channel, $s\,m$, provided the head, $h = n\,s$, be maintained constant.

The flow may be increased nearly to the theoretical value ($v = \sqrt{2\,g\,h}$, or $c = 1$) by neatly **rounding off the edges** of the entrance end or mouth of the tube, as in Fig. 7, which represents, half-size, one with which Weisbach obtained $c = 0.975$ when $h = 10$ ft, and $c = 0.958$ when $h = 1$ ft

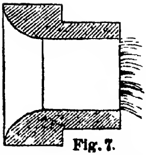

Fig. 7.

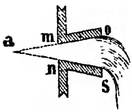

Fig. 8.

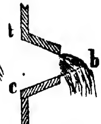

Fig. 9.

As much as .92 to .94 may be obtained by widening the opening, *m n*, toward its outer mouth, *o s*, Fig, 8, making the divergence, or angle *a*, about 5°, or by widening it toward its inner mouth, as at *t c*, Fig 9, but increasing the angle of divergence, at *b*, to from 11° to 16°. In all cases, we consider the small end as being the opening whose area must be multiplied by the vel to get the discharge.

In some experiments made with large pyramidal wooden troughs 9.5 ft long, with an inner mouth of 3.2 × 2.4 ft, and a discharging one of .62 × .44 ft; and under a head of 9⅓ feet, the discharge was .98 of the theoretical one, due to the smaller end.

Rem 5. With an adjutage shaped as in Fig 10, about 9 ins long; diams, *m n* = 1 inch, and *b c* = 1.8 ins, Venturi and Eytelwein obtained a discharge = $1.55\ a\ \sqrt{2\ g\ h}$; where *a* = the smaller cross section area at *m n*, and *h* = distance from to free water surface.

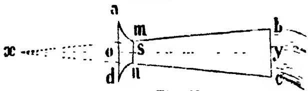

Fig. 10.

See the Venturi Meter, Art 4 *a*.

Art. 9. On the disch of water through openings in thin vert partitions, with plane or flat faces, *e e*, or *n n*, Fig 11.* If the face *e e*, or *n n*, instead of being plane, and vert, should be curved, or inclining in diff directions toward the opening then the disch will be altered When water flows from a reservoir, Fig 11, through a vert plane plate or partition *n n*, which is not thicker than about the least transverse dimension of the opening, whether that dimension be its breadth, or its height *o o*, † or when, if the partition *e e* itself is much thicker, we give the opening the shape shown at *b*, (which evidently amounts to the same thing) then the effluent stream will not pass out with a *full flow* as in Fig 6 but will assume the shape shown in Fig 11, forming, just outside of the opening, what is called the *vena contracta*, or *contracted vein*. In order that this contraction may take place to its fullest extent, or become *complete*, the inner sharp edges of the opening must not approach either the surf of the water, or the bottom or sides of the reservoir, nearer than about 1⅓ times the least transverse dimension of the opening. The contracted vein occurs at a dist of about half the smallest dimension of the orifice, from the orifice itself. In a circular orifice, at about half the diam dist: and ordinarily its area is about .62 or nearly ⅝ that of the orifice itself. At this point the actual mean *vel* of the stream is very nearly (about .97) the theoretical vel given by Table 10, and hence the actual *dischs* are but .62, or nearly ⅝ of the theoretical ones.

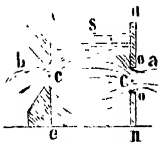

Fig. 11.

Case 1. **To find the actual disch into air,† through either a circular or rectilinear§ opening in a thin vert plane parti-**

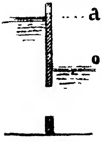

Fig. 12.

* We believe that these rules for thin plate are also sufficiently approximate for most practical purposes, if the opening be in the *bottom* of the reservoir; or in an *inclined*, instead of a *vert* side.

† When the side of a reservoir, or the edge of a plank, &c. over which water flows, has no greater thickness than this, the water is said to flow through, or over, **thin plate,** or **thin partition.**

‡ Should the disch take place *under water*, as in Fig 12, *both surf-levels remaining constant*, then the head to be used is the *vert* diff *a o*, of the two levels After making the calculation with this head, we should, according to Weisbach, deduct the $\frac{1}{75}$ part; inasmuch as he states that the disch is that much less when under water, than when it takes place freely into the air. Other experimenters, however, assert that it is precisely the same in both cases.

§ If the shape of the opening is oval, triangular, or irregular, the head must be measured vert from its cen of grav.

tion, when the contraction is complete; and when the surf. level, *s*, remains constantly at the same height: water being supplied to the reservoir as fast as it runs out at the opening.*

Rule 1. When the head, measured vert from the center (or rather from the cen of grav) c, of the opening, to the surf level *s* of the reservoir, is not less than 1 ft, nor more than 10 ft; and when the least transverse dimension of the opening is not less than an inch, mult the theoretical vel in ft per sec due to the head. (Table 10,) by the coefficient of disch .62. The prod will be the actual mean vel of the water through the opening. Mult this vel by the area of the opening in sq ft; the prod will be the disch in cub ft per sec, approximately.

When the head is greater than 10 ft, use .6, instead of .62

Rule 2. Find the sq rt of the head in ft. Mult this sq rt by 5, the prod will be the vel in ft per sec; which mult by the area as before for the disch

Ex. What will be the disch through an opening in complete contraction, whose dimensions are 6 ins, or .5 ft vert, and 4 ft hor; the vert head above the cen of grav of the opening being constantly 6 feet?

By Rule 1. The theoretical vel (Table 10, corresponding to 6 ft head, is 19.7 ft per sec And 19.7 × .62 = 12.214 ft, the reqd vel. Again, the area of the opening = .5 × 4 = 2 sq ft, and 12.214 × 2 = 24.428 cub ft per sec, the disch

By Rule 2. The sq rt of 6 = 2.45; and 2.45 × 5 = 12.25 ft per sec, the reqd vel; and 12.25 × 2 = 24.5 cub ft per sec, the disch.

Both very approx even if the orifice reaches to the surface of the issuing water.

Rem. 1. The coef .62 is a mean of results of many old experimenters In 1874 Genl. T. G. Ellis of Massachusetts conducted an elaborate series (Trans Am Soc C E, Feb 1876) on a large scale, the general results of which, within less than 1 per ct, are given in the following table. See also Rem 3. The sharp edged orifices were in iron plates .25 to .5 inch thick

Orifice.	Head above Center.	Coef.
2 ft sq.	2 to 3.5 ft	.60 to .61
2 " long, 1 ft high	1.8 to 11.5 "	.60 to .61
2 " long, .5 high	1.4 to 17.0 "	.61 to .60
2 " diam.	1.8 to 9.6	.59 to .61

Rem. 2. Extreme care is reqd to obtain correct results, but for many purposes of the engineer an error of 5 to 10 per ct is unimportant

It will rarely happen that greater accuracy is required than may be obtained by the foregoing rules; but when such does occur, aid may be derived from the following **table deduced from the experiments of Lesbros and Poncelet**, on openings 8 ins wide, of diff heights, and with diff heads Use that coeff in the table which applies to the case, instead of the .62 of Rule 1 In some of the cases in this table, the upper edge of the opening is nearer the surf level of the reservoir than 1½ times its least transverse dimension

TABLE 12. Coefficients for rectangular openings in thin vertical partitions in full contraction.*

Head above cen. of grav. of opening in Feet.	Head above cen. of grav. of opening in Inches.	The breadth in all the openings = 8 inches. HEIGHT OF OPENING Ins. 8	Ins. 6	Ins. 4	Ins 3	Ins 2	Ins. 1	Ins .4

10	120	.60	.60	.60	.60	.60	.61	.61

Rem. 3. Careful experiments on openings 4¼ ft wide, and 18 ins high, under heads of from 6 to 15 ft, gave coeff = 0.62, correct within about 3 per cent, although the thickness of the partition varied, on its diff sides from 12 to 20 ins.

Rem. 4. When two or more contiguous openings discharge at the same time from the same reservoir, they appear to disch the same as, or a little less than, a single orifice of their combined size.

Case 2. **The discharge through thin vert partitions in complete contraction, when the surface-level, *m*, Fig 13, descends as the water flows out into the air.** In this case, if the reservoir is prismatic, that is, if its hor sections are everywhere equal; and if no water is flowing into the reservoir, to supply the place of that which flows out, then, to find the time reqd to disch the reservoir.

RULE. Inasmuch as the time in which such a reservoir entirely discharges itself, is twice that in which the same quantity would flow out under a constant head, as in Case 1, therefore, calculate the disch in cub ft per sec by Rule 1, Art 9, div the number of cub ft contained in the reservoir, above the level *g* of the bottom of the opening, Fig 13, by this disch, the quot will be the number of sec in which a volume equal to that in the reservoir, to the depth *g*, would run out in Case 1, of a *constant* head. And *twice* this number will be the seconds reqd to empty the reservoir in Case 2, of a *varying* head.

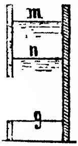

Fig. 13.

EX. If it should be reqd to find the time in which such a prismatic reservoir would *partly* empty itself, as, for instance, from *m* to *n*, Fig 13, first calculate, by the above rule, the secs necessary to empty it if it had only been filled to *n*; and afterward calculate as if it had been filled to *m*. The diff between the two times will evidently be the time reqd to empty it from *m* to *n*. If the opening is not in complete contraction, see Arts 11, &c.

If the disch is into a lower reservoir, whose surf-level remains constant, proceed in the same manner; only use the diff of level of the two surfs as the head, and afterward (according to Weisbach) increase the time $\frac{1}{75}$ part.

Art. 10. Disch from a reservoir R, Fig 14, the surf-level, *s*, of which remains constantly at the same height; through an opening, *o*, in thin vert partition; and in complete contraction; but entirely under water; and into a prismatic reservoir, *m*.

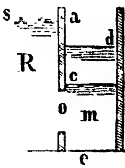

Fig. 14.

Seconds required to discharge a quantity *c d a*, *the level c remaining constant*:

$$= \frac{\sqrt{\text{height } a\,c \text{ in ft}} \times \text{hor area of } m \text{ in sq ft}}{\text{area of opening } o \text{ in sq ft} \times .62 \times 8.03}$$

Seconds required *to raise level in m from c to a*:

$$= \frac{\sqrt{\text{height } a\,c \text{ in ft}} \times \text{hor area of } m \text{ in sq ft} \times 2}{\text{area of opening } o \text{ in sq ft} \times .62 \times 8.03}$$

Seconds required *to raise level in m from c to any other level, d*:

$$= \frac{\left(\sqrt{a\,c} - \sqrt{a\,d} \text{ both in ft}\right) \times \text{hor area of } m \text{ in sq ft} \times 2}{\text{Area of opening } o \text{ in sq ft} \times .62 \times 8.03}$$

REM. 1. **If it should be reqd to find the time of filling *m*, from its bottom *e*, up to *d*,** we may do so very approximately by calculating by the first rule in Art 9, the time reqd from *e* to the center of the opening *o*, as if all that portion of the disch took place into air; and afterward, from the center of the opening to *d*, by the rule just given. This case is similar to that of filling a lock from the canal reach above, in which the surf-level may be considered constant.

REM. 2. **If the bottom of the opening *o*, should coincide with the bottom of the reservoir,** then the coeff will become greater than .62. See Art 11, for obtaining coeffs for imperfect contraction.

REM. 3. **If the opening, instead of being in complete contraction,** is of any of the shapes Figs 6 to 9, then a reference to Art 8 will show what coeff must be substituted for .62.

Case 3. **Disch from one prismatic reservoir, Fig 15, W, into another, X, of any comparative sizes whatever, through an opening *o*, in a plane thin vert partition, and in complete contraction; when the water rises in X, while it falls in W.**

To find the time in which the water, flowing from W into X, through o, will fall through the dist a s, so as to stand at the same level s c, in both reservoirs.

In this case, the water reqd to fill X from *e* to *d*, (*d* being the bottom of the opening *o*,) flows out into the air; and the time necessary for it to do so, must be calculated separately from that reqd above *d*, which flows into water.

RULE. First from *e* to *d*. Find the hor area of each reservoir, in sq ft. Mult the hor area of X, by the vert depth *d e* in ft, for the cub ft contained in that portion. Div these cub ft by the hor area of W. The quot will be the dist *a m*, in feet, through which the water in W must descend, in order to fill X to *d*.

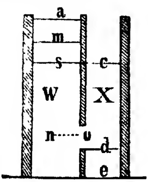

Fig. 15.

Seconds required to lower from *a* to *m*, and raise from *e* to *d*:

$$= \frac{\text{Twice the hor area of W in sq ft} \times \left(\sqrt{\text{head } a\,n \text{ in ft}} - \sqrt{\text{head } m\,n \text{ in ft}}\right)}{\text{Area of opening } o \text{ in sq ft} \times .62 \times 8.03}$$

$$\textbf{Seconds required}\ \text{to lower from } m \text{ to } s\text{, and raise from } d \text{ to } c\text{. (Very approx)} = \frac{\begin{matrix}\text{Hor area of}\\ \text{X in sq ft}\end{matrix} \times \begin{matrix}\text{twice the hor area}\\ \text{of W in sq ft}\end{matrix} \times \sqrt{\begin{matrix}\text{head } m\ s\\ \text{in ft}\end{matrix}}}{\begin{matrix}\text{Area of}\\ \text{opening}\\ o \text{ in sq ft}\end{matrix} \times \left(\begin{matrix}\text{hor area}\\ \text{of W}\\ \text{in sq ft}\end{matrix} + \begin{matrix}\text{hor area}\\ \text{of X}\\ \text{in sq ft}\end{matrix}\right) \times .62 \times 8.03}$$

Ex Let the hor area of W be 100 sq ft; and that of X, 60 sq ft Let *a n* be 20 ft, and *m n* 16 ft, and the area of the opening *o*, 3 sq ft. In what time will the water descend from *a* to *s*, and rise from *e* to *c*?

Inasmuch as the method of finding the time for filling from *e* to *d*, by the water falling from *a* to *m*, requires no further exemplification, we will confine ourselves to the *additional* time necessary for filling from *d* to *c*, by the water falling from *m* to *s*. To find this, we have, the sq rt of the head $m\ n = 4$ ft, and the sum of the 2 areas $= 100 + 60 = 160$. Hence, $\frac{4 \times 100 \times 60 \times 2}{160 \times 8.03 \times 3 \times .62} = \frac{48000}{2389.73} =$ 20 1 sec, the additional time reqd, very approximately.

NOTE 1. **If the opening, as *d*, Fig 16, reaches to the very bottom of the reservoirs,** we may consider all the water flowing from R into T, as flowing into water. Therefore, using the head *a m*, we at once calculate the time necessary for the water in the two reservoirs to arrive at the same level *s c*, by the last process of the preceding rule, or, in other words, by the process given in the preceding example. But in this case it must be borne in mind that the opening *o* is no longer in *complete* contraction, inasmuch as the contraction along its lower edge is suppressed.

The disch will consequently be somewhat increased, and a coeff greater than .62 becomes necessary. The method of finding this, is given in the following Case 4. A reference to Art 8 will give the coeff in case the opening is shaped as Figs 6 to 9.

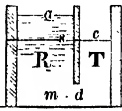

Fig 16.

Art. 11. *Case* 4. The discharge through openings in plane thin vert partitions; but in incomplete contraction.

The opening may be such that contraction will take place along one portion of its perimeter, or at the top of the opening *a*, Fig 17, while it is suppressed on another portion; as at the bottom and two ends of the opening *a*; where suppression is caused by the addition of *short* side and bottom pieces *c, c, c*. Or it may be caused by the bottom, or ends, or both, coinciding with the bottom and sides of the reservoir. In such cases the disch will be greater than in those of complete contraction; but less than in those of full flow, inasmuch as the opening now partakes somewhat of the character of the *short* tubes of Art 8; and the coeff will rise from .62, or that which *usually* pertains to openings in full contraction; and will approach .8, or that of full flow, in proportion to the extent of perimeter along which contraction is suppressed, or even to .9 or .98 by the use of such openings as are shown by Figs 7, 8, 9.

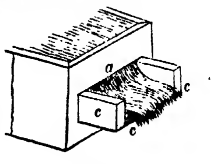

Fig. 17.

To find approximately a new coeff of disch; and the disch itself, in cases of incomplete contraction.

RULE. First find by the foregoing rules, what would be the disch in the particular case that may be under consideration, supposing the contraction to be complete. Then div that portion of the perimeter of the opening on which contraction is suppressed, by the entire perimeter. Mult the quot by the dec .152 if the opening is rectangular, or by .128 if circular To the prod add unity, or 1. Call the sum, *g*. Then say, as unity, or 1, is to *g*, so is the coeff for complete contraction in ordinary cases (usually .62) to the reqd new coeff Finally, repeat the original calculation, only substituting this new coeff in the place of .62.

According to this rule, we have the following coeff of discharge for rectangular openings within probably 3 or 4 per cent, when contraction is not suppressed on more than ¾ of the perimeter. The theoretical discharge multiplied by the corresponding coeff will give the actual discharge. When the contraction is carried farther, the coeff becomes extremely irregular, and is probably indeterminable.

For complete contraction (ordinarily)	.62
When contraction is suppressed on ¼ *the perimeter*	.64
" " " " " ½ " "	.67
" " " " " ¾ " "	.69
" " " " *entirely around the orifice*	.80

Intermediate ones can be estimated nearly enough, mentally

Art. 12. Fig. 18 **Contraction suppressed at the bottom and at both vert sides of the opening o, in consequence of their coinciding with the bottom and sides of the reservoir.** Front of reservoir sloped, as at *f*. Use Rule 1, Case 1, Art. 9; but, according to Poncelet, the coefficient, instead of 0.62, as in Rule 1, should be 0.80 if *f* slopes 45°, or 1 : 1; and coeff = 0.74 if *f* slopes 63° 30′, or 1 hor : 2 vert.

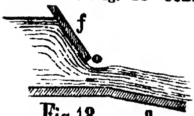

Fig 18

Art. 13. To find, approximately, the time reqd for the emptying of a pond, or any other reservoir, as Fig 19, which is not of a prismatic shape; through an opening, *n*, near the bottom.

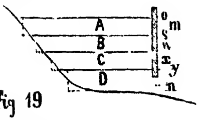

Fig 19

RULE. First ascertain the exact shape and dimensions of the reservoir. If large, and irregular, it must be carefully surveyed, and soundings taken, and figured upon a correct plan and cross-sections. Next, consider the entire body of water to be divided into a series of thin hor strata. A, B, C, D, the top line of the lower one being at least a few ins above the top of the opening *n*. It is not necessary that these strata should be of equal thickness; although the thinner they are, the more correct will the result be. The depth of the lower one, D, will vary to some extent with the height of the opening; those next above it should not exceed about a foot in thickness, until a depth of 6 or 8 feet is reached; then they may conveniently, and with sufficient accuracy, be increased to about 2 ft, for 6 or 8 ft more; and so on; becoming thicker as they approach the surf. By aid of the drawings, calculate the content of each stratum in cub ft. Now, since the strata are thin, we may, without serious error, assume each of them to be prismatic, as shown by the dotted lines; and may assume that the head under which each stratum (except the lowest) empties itself through *n*, is equal to the vert height from the center of the opening to the center of the stratum. Thus, *m n* will be the head of A; *w n*, the head of B; *x n*, the head of C. Then, for the stratum A, by Rule 1, Art 9, (only using *m n* as the head instead of *o n*,) and instead of the coeff .62 of that rule (which can only be used if *n* is in complete contraction) using .64, or whatever other coeff near the end of Art 11 applies to the case, calculate the disch in cub ft per sec. Div the content of the stratum A by this disch, and the quot will be the number of sec reqd for discharging A. Using the head *w n*, proceed in precisely the same way with the stratum B; and using the head *x n*, do the same with C. Finally, for the lower stratum D, find by Rule 1, Art 9, (with the same caution as before respecting the proper coeff.) in what time it would empty itself under a *constant* head equal to *y n*, measured from its *surf* to the center of the opening. *Double* this time will be that reqd to empty itself in the case before us, under its *varying* head. Finally, add together all these separate times; and their sum will be the entire time reqd to empty the pond, or reservoir, approximately enough for practical purposes.

(*f*) **The length L of the crest,** Figs. 21 to 22 *a*, should be at least three times the head H, in order to reduce the effect of friction of the sides *s s* and that of end contractions where such exist. **The height** *p*, Fig. 20, of the vertical back *a b* in contact with the water should be not less than twice the head H; for, in order to reduce the velocity of approach (see Art. 14 *u*), the cross-section of **the channel** leading to the weir should be large in proportion to that of the stream *a c*. The cross-section of the channel of approach should be as *regular* as possible.

(*g*) The weir should be stoutly built, as **vibrations** of the structure may seriously modify the discharge

(*h*) *Theoretically*, **the head** is the vertical distance H', Fig. 24, from the crest *a* to a point *o'* where the water is *perfectly still*, and the surface therefore *horizontal*. But in fact the head is usually measured from the crest *a* to a point *o* a few feet back from the weir where the water is only *comparatively* still, the velocity of approach being perceptible (See Art. 14, *u*.) The difference between the head H actually measured and the head H' to *still* water is usually very slight. It is greatly exaggerated in the figure.

The correct **measurement of the head** is a delicate matter, the discharge being increased or diminished about $1\frac{1}{2}$ per cent. by 1 per cent of increase or diminution of the head Waves or ripples and other disturbances of the surface, and capillary attraction, are the chief sources of error.

(*i*) To avoid the latter difficulty, the **hook-gauge** is used for measuring the height of the water surface in important cases. This consists of a long graduated rod, provided at its *foot* with an upturned hook or point, and sliding vertically (by means of a screw motion) in a fixed support, to which is attached a vernier indicating on the scale the height of the point. The sliding rod is first run down until the point is well below the surface, and then gradually raised by means of the screw until the point just reaches the surface, which is indicated by the first appearance of a "pimple" in the water surface immediately over the hook Under favorable circumstances a good hook-gauge may be read within from .0002 to .0005 foot

(*j*) To avoid inaccuracies due to the **disturbance of the surface** by the current, by wind, etc., the level is sometimes taken (with the hook-gauge or otherwise) in a side chamber which communicates with the main channel of approach. The surface in the chamber maintains the same level as that in the channel itself, but is comparatively free from disturbance Or a bucket communicating with the channel by means of a pipe can be made to serve in the same way Either may of course be sheltered from the wind **Caution.** Messrs Fteley and Stearns found that when the bucket or chamber communicated with the water *near the bottom and close behind the weir*, the head thus obtained was generally somewhat greater than that found by measurement near the surface and 6 feet back from the weir. But Mr. Francis found the difference scarcely perceptible.

(*k*) Great care is necessary in **adjusting the hook-gauge for the height of the crest;** for any error in this affects all the subsequent experiments. The hook is usually adjusted to the height of the surface when the latter just reaches the level of the crest; but this method is rendered inaccurate by capillary attraction at the crest A more accurate method is to have, in addition to the hook-gauge, a stout *fixed* hook, pointing upward, the level of which, relatively to that of the crest, may be ascertained by means of an engineer's level, holding the rod on the crest and also on the point of the fixed hook. The water surface is then allowed to fall slowly until a "pimple" just appears over the fixed hook. It is then kept at that level and the hook-gauge adjusted accordingly. Or if the gauge-hook is a stout one, the levelling rod may be set at once upon its point without having recourse to a fixed hook. It is better to adjust the hook-gauge so as to read *zero* for the crest level, which is thus made the datum; for the reading of the hook-gauge for the water surface then gives the head H at once, and without subtracting the height of the crest.

(1) Formulæ for weir discharge.
Let

Q = the actual discharge over the weir, in cubic feet per second; *
Q' = the theoretical discharge over the weir, in cubic feet per second,
H = **H'** † = the vertical distance or head *a m*, Fig. 24, p. 556, in feet,* measured from the crest *a* to the *horizontal* surface *o'* of *still* water up-stream from the weir;
L = the length *a a* of the weir, in feet,* Figs 21 to 22 *a*;
g = the acceleration of gravity = say 32.2 feet * per second per second;

$$\left.\begin{aligned} c &= \text{coefficient of discharge} = \frac{\text{actual discharge}}{\text{theoretical discharge}} = \frac{Q}{Q'}; \\ m &= \frac{2}{3}c, \\ x &= \frac{2}{3}c\sqrt{2g} = m\sqrt{2g} = \text{say } 5.36\,c = \text{say } 8.025\,m. \end{aligned}\right\}\ddagger$$

Then, for the **theoretical discharge,** we have

$$Q' = \frac{2}{3}\,L\,H\sqrt{2gH}; \S \ldots\ldots \quad (1)$$

and for the **actual discharge,**

$$\left.\begin{aligned} Q &= c\,Q' \\ &= \frac{2}{3}c\,L\,H\sqrt{2gH} \ldots\ldots\ldots\ldots \quad (2) \\ &= m\,L\,H\sqrt{2gH} \ldots\ldots\ldots\ldots \quad (3) \\ &= x\,L\,H\sqrt{H} = x\,L\sqrt{H^3} = x\,L\,H^{\frac{3}{2}} \ldots \quad (4) \end{aligned}\right\}\text{See foot-notes } *\dagger\ddagger$$

For the value of the coefficient (*c*, *m*, or *x* ‡) we have recourse to experiment, measuring the actual discharge and comparing it with the theoretical one, as in the following articles.

---

* The formulæ apply equally to any system of measures, as the English, the metric, etc. It is requisite merely that the units, of length, of time, etc., used, be the same throughout. In metric measure, g = 9.81 meters per second per second.

† *For the present* we suppose the head to be measured to *still* water, so that H = H'. When this is not the case, see "Velocity of Approach," Art. 14 (*a*), etc.

‡ It will be noticed that the formulæ (2), (3) and (4), with their corresponding coefficients, *c*, *m*, and *x*, are really identical, differing only in form. The last is the most convenient in practice, but all are met with in works on hydraulics.

§ When water issues under a head H, from a *horizontal* orifice in the *bottom* of a vessel, the theoretical velocity (Art. 7, is $= \sqrt{2gH}$; and this may be regarded as true also for *vertical* orifices in the *sides* of vessels, provided the head H to the center of gravity of the orifice is at least two or three times the vertical dimension of the orifice; for in both cases the theoretical velocities through the several parts of the orifice may be taken as *equal*. But when a vertical orifice is nearer to the surface, or when it *reaches* to the surface as in the case of a weir, we must take into consideration the differences in the velocities with which the water issues from points at different depths.

Theoretically, the particles pass the oblique plane *a o'*, Fig. 23, in horizontal lines, with velocities ($= \sqrt{2gh} = 8.025\sqrt{h}$) proportional to the square roots of their several vertical depths *h* (not indicated in fig.) below still water surface at *o'*. Therefore if from *a m* we imagine horizontal lines *a a'*, *d d'*, *v v'*, *c c'*, etc., etc., to be drawn, representing all these velocities to any scale, then the outer ends *a'*, *d'*, *v'*, *c'*, etc., etc., of these lines will form, with *a m* and *a a'*, a parabolic segment *a m c' a'*, the area of which is:

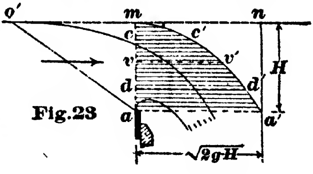

Fig.23

area $= \frac{2}{3}$ area of rectangle *a n* (see Parabola, p. 192) $= \frac{2}{3}\,a\,m \times a\,a' = \frac{2}{3}\,H\sqrt{2gH}$; and this area in square feet, multiplied by the thickness of the escaping sheet of

(*m*) **Mr. James B. Francis*** experimented at "the lower locks," Lowell, Mass., in 1852, with weirs 10 feet long, 5 feet and 2 feet high, under heads from 7 to 19 inches. To apply his results, the following conditions must exist:

The head H, Fig 20, must be between 6 and 24 inches. The height p of the vertical back of the weir above the bottom b of the channel must be at least twice the head H. The crest a must be "in thin partition" (foot-note † p 541), and its length L, Figs. 21 to 22 a, must be at least 3 times the head H. The ends $a\,h$, $a\,h$ must be vertical, and, when there is end contraction, "in thin partition."

When there is end contraction, Mr. Francis first deducts from the actual length L of the weir *one tenth* † *of the head* H for *each* end where contraction occurs. Thus, if n = the number of end contractions (two in Fig. 22),

$$Q = x\left(L - n\,\frac{H}{10}\right) H\,\sqrt{H} = x\left(L - n\,\frac{H}{10}\right) H^{\frac{3}{2}} \ddagger \quad \ldots \quad (5)$$

$$\text{In Fig. 22, } Q = x\left(L - \frac{H}{5}\right) H\,\sqrt{H}.\dagger = x\left(L - \frac{H}{5}\right) H^{\frac{3}{2}}$$

But within the limits specified above, the formula is very approximate *without* correction for end contraction, provided the length L of the weir is at least 10 times the head H; and within 6 per cent. of the truth when L is = 4 H. When there is no end contraction, of course no such correction is required, and the formula remains $Q = x\,L\,H\,\sqrt{H}\,\dagger = x\,L\,H^{\frac{3}{2}}$.

Mr. Francis gives x = 3.33 for *feet*; § or

$$\textbf{Discharge} = 3.33 \times \left(\text{length} - \frac{\text{number of}}{\text{end contractions}} \times \frac{\text{head H}}{10}\right) \times H^{\frac{3}{2}}, \ddagger$$

the mean of his 88 experiments being 3.3318. The least value of x obtained by him was 3.3002, or 1 in 112 less than 3.33; and the greatest was 3.3617, or 1 in 105 more than 3.33. Hence, with x = 3.33, the formula will give the discharge for each of his experiments within 1 per cent. In 67 out of the 88 experiments x ranged between 3.32 and 3.35, and in 53 between 3.32 and 3.34. When x is 3.33, **m** is = 0.415, and **c** is = 0.622

The height of the surface was measured six feet back from the weir by two hook-gauges, one on each side of the channel; and the mean of their readings was used in calculating the coefficient x.

---

water, or length L of weir, in feet, gives the theoretical discharge in cubic feet per second. Or

$$Q' = L \times \text{area } a\,m\,c'\,a' = L \times \frac{2}{3} H\,\sqrt{2\,g\,H}.$$

Hence, area $a\,m\,c'\,a'$ in sq. ft. represents the theoretical disch. in cub. ft. per sec. over 1 ft. length of weir, under head H. The theoretical *mean vel.* through the section $a\,o'$ is

$$V = v\,v' = \frac{\text{theoretical discharge } Q'}{\text{area } a\,m} = \frac{2}{3}\,L\,H\,\sqrt{2\,g\,H} \div L\,H = \frac{2}{3}\sqrt{2\,g\,H},$$

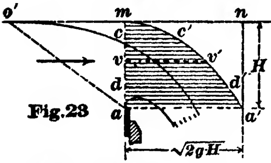

Fig.23

or two thirds of the theoretical horizontal velocity $a\,a'$ of the particles passing immediately over the weir. As in the case of orifices (Art. 9, p. 541), the actual vel. *at the smallest section* of the sheet after passing the weir (corresponding to the "vena contracta") is probably very nearly equal to this theoretical velocity.

* "Lowell Hydraulic Experiments," Van Nostrand, New York, 1883.

† In Messrs. Fteley and Stearns' experiments this figure was not constant at 0.10, but varied between 0.061 and 0.124, generally increasing as the head decreased.

‡ We here suppose the head to be measured to the surface of *still* water, so that H and H' (see Art. 14 *h*, p. 548) are the same. See Velocity of Approach, Art. 14 (*u*).

§ Since 1 meter = 3.2808 ft., the value of x for metric measure corresponding to Mr. Francis' 3.33, is = 3.33 ÷ $\sqrt{3.2808}$ = 3.33 ÷ 1.8113 = 1.838

Table 13.* **Discharge in cubic feet per second for each foot in length of weir** in thin plate and without end contraction, by the Francis formula: **Discharge,** Q/L, per foot of weir length, $= 3.33\ H^{\frac{3}{2}} = 3.33\ H\sqrt{H}$.

Very approximate also when there is end contraction, provided that L is at least = 10 H; and but about 6 per cent. in excess of the truth if L = 4 H. Mr. Francis limits the formula to heads H from 0.5 foot to 2.0 feet, but no serious error will result from using the table for any of the heads given. **For weirs of other lengths** than 1 foot, multiply the tabular discharge by the actual length in feet.

H = head, in ft; **Q/L** = disch in cu ft per sec per weir-lgth ft

* Table 13 is an extension of the "original" table published in our first edition, 1872. Most of the values now given are taken, by permission, from a table published by Messrs. A. W. Hunking and Frank S Hart, of Lowell, Mass., in May, 1884.

(*n*) **Messrs. A. Fteley and F. P. Stearns** * experimented at Boston, Mass., in 1877–79, upon weirs 5 feet and 19 feet long, 3 feet 2 inches and 6 feet 6¼ inches high, and under heads from 0.8 inch to 19 inches. For weirs in thin partition and without end contraction, with a rectangular and uniform channel of approach and under heads greater than 0.07 foot or 0.84 inch (other conditions as specified in (*b*) and (*d*)), their formula is:

$$\textbf{Discharge, } \left.\begin{aligned} Q &= 3.31\ L\ H^{\frac{3}{2}} + 0.007\ L \\ &= 0.4125\ L\ H\ \sqrt{2\,g\,H} + 0.007\ L \end{aligned}\right\}\dagger \quad \ldots \ (6).$$

In their experiments, the heads were measured six feet back from the weir. The total variation in the values of the coefficients obtained was about 2½ per cent. Compare foot-note § below.

(*o*) **M. Bazin** ‡ experimented at Dijon, France, in 1886–88, with weirs from about 1½ to 6½ feet long, from about 9 inches to 3 feet 9 inches high, and under heads from 2½ to 21 inches. The top of the weir is shown in Fig. 23 *a*. The weirs were placed at different points in a rectangular and regular canal 700 feet long, smoothly lined with cement. Compare foot-note § below.

While Mr. Francis and Messrs. Fteley and Stearns provide for the effect of velocity of approach (see Art. 14 *u* and *v*) by modifying the measured *head* H, M. Bazin includes it in the *coefficient m* in the formula $Q = m\ L\ H\ \sqrt{2\,g\,H}$.

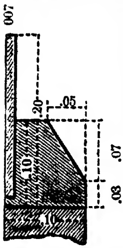

Fig. 23 a.
Measurements in meters.

Let M = the value of *m* for the case where velocity of approach = 0. Then, very approximately:

$$M = 0.405 + \frac{0.003}{H\ \text{meters}} = 0.405 + \frac{3.28 \times 0.003}{H\ \text{feet}} = 0.405 + \frac{0.00984}{H\ \text{feet}}$$

When velocity of approach is to be taken into account:

$$\mathbf{m} = M\left[1 + 0.55\left(\frac{H}{H + p}\right)^2\right] \ldots \quad \ldots (7);$$

where H is the head actually measured to running water, and *p* is the height *a b* of the weir, Fig. 20. H and *p* must of course both be measured in the same unit, as both in meters, or both in feet, etc.

M. Bazin believes that except in the case of very low weirs (which should be avoided) the values of *m* given by formula (7) and in Table 14 calculated from it, will be found within 1 per cent. of the truth for weirs in thin partition and without end contraction, if the conditions of his experiments are exactly reproduced, and provided especially that the sheet of water is not allowed to expand laterally after passing the crest (Art. 14 (*d*)) and that the air has free access to the space *w*, Fig. 20, behind the falling sheet of water.

For heads between 4 inches and 1 foot, M. Bazin gives, as sufficiently approximate,

when there is no velocity of approach, M = 0.425,§

and, to allow for velocity of approach, $\mathbf{m} = 0.425 + 0.21\left(\frac{H}{H + p}\right)^2$.

* Transactions, American Society of Civil Engineers, Jan., Feb. and March, 1883.

† See correction for Velocity of Approach, Art 14 (*u*).

‡ Expériences nouvelles sur l'écoulement en déversoir. Extrait des Annales des Ponts et Chaussées, Oct., 1888. Paris, Vve Ch. Dunod, 1888. Translation by A Marichal and John C. Trautwine, Jr., presented to Engineers' Club of Philadelphia, in 1889, for publication in its Proceedings.

§ This would make $x = 3.41$ (since $x = m\sqrt{2\,g} = 8.025\ m$); whereas Mr. Francis gives $x = 3.33$, which agrees very well with Messrs. Fteley and Stearns, within the limits of Art. 14 (*m*). Yet M. Bazin measured the head 16 feet back from the weir, while the other experimenters measured it only 6 feet back, and the slight increase of head thus obtained by M. Bazin would of itself have made his coefficient *lower* than theirs. Its excess may be largely due to the character of the channel of approach, which in his case was from 50 to 700 feet long, rectangular and regular in cross-section, and smoothly coated with cement. In the other experiments it was much less regular.

Table 14. Values of Bazin's m, in the formula:

$$Q = m\,L\,H\,\sqrt{2\,g\,H}.*$$

The coefficient, $m = \frac{2}{3}\,c = \frac{2}{3}\cdot\frac{Q}{Q'}$, p. 549, being a mere ratio, is independent of the unit of length adopted; but *Bazin's* M and *m* include correction for velocity of approach. They therefore depend upon the unit in which H is expressed. See p. 552.

Using Bazin's *m*, as given in the table below, we have, for the **discharge** per second:

Cubic *meters* = *m* × length L in met. × head H* in met. × $\sqrt{2 \times 9.81\ \text{H in met.}}$;

Cubic *feet* = *m* × length L in feet × head H* in feet × $\sqrt{2 \times 32.2\ \text{H in feet.}}$

It will be noticed that **below the heavy lines** the head H is greater than ½ height *p*, and thus exceeds the limit laid down in (**f**) and (**m**).

Owing to the wide range of the head H and of the height *p* in these experiments, we find in them **a wider divergence** in the values of the coefficient than resulted from the earlier investigations Thus, the smallest value of *m* above the heavy lines is 0.4092, or about one nineteenth less than the mean, 0.4325; and the greatest is 0.459, or about one sixteenth more than 0.4325.

* In these experiments, the head H was measured at a point 5 meters (16.4 ft) back from the weir. The correction for velocity of approach is contained in the coefficient *m*.

† M is the value of *m* when there is no velocity of approach; *i. e.*, where the cross-section of the channel of approach is indefinitely great compared with that of the stream of water passing over the weir.

(*p*) From a comparison of a number of experimental data, **the author** deduced the following

Table 15. Approximate values of the coefficient m in the formula:

$$Q = m\,L\,H\,\sqrt{2\,g\,H},$$

for weirs of several different shapes and thicknesses. (Original)

(*q*) **To find the head H, approximately;** having the discharge Q According to formulæ (3) and (4), Art. 14 (*l*).

$$Q = m\,L\,H\,\sqrt{2\,g\,H} = x\,L\,H\,\sqrt{H} = m\,L\,\sqrt{2\,g}\,\sqrt{H^3}, = x\,L\,\sqrt{H^3},$$

Hence

$$H = \sqrt[3]{\frac{Q^2}{m^2\,L^2\,2\,g}} = \sqrt[3]{\frac{Q^2}{x^2\,L^2}} \quad . \quad . \quad (8)$$

or

$$\textbf{Head, } H, \text{ approximately} = \sqrt[3]{\frac{\text{square of discharge of stream, in cub. ft. per sec.}}{m^2 \times \text{length}^2 \times 64.4}}$$

$$= \sqrt[3]{\frac{\text{sq. of discharge}}{x^2 \times \text{length}^2}}$$

The coefficient *m* or *x* itself varies somewhat with the head; but the formula may be usefully employed as an approximation by taking, for sharp-crested weirs, $m = 0.415$ ($m^2 = 0.172$) or $x = 3.33$ ($x^2 = 11$). For other shapes, see Table 15, above.

(*r*) **Submerged weirs,** Fig 23 *b*, are those in which the surface of the *down*-stream water at *h*, after the construction of the weir, is *higher* than the crest *a*.

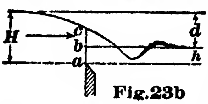

Fig.23b

In a weir discharging freely into the air, as in Fig. 20, Mr. Francis found that with a head of 1 foot the discharge was diminished only about one thousandth part by placing a solid horizontal floor about 6 inches below and in front of the crest of the weir for the water to fall upon. Also, when the head was 10 inches, and the water fell freely through the air into water of considerable depth (as in Fig 20), the quantity discharged was the same whether the surface of the down-stream water was about 3 inches or about 13 inches below the crest *a*.

In experiments by Mr. Francis and by Messrs Fteley and Stearns, with air freely admitted underneath the falling sheet of water just below the crest *a*, the discharge was not appreciably affected by a submergence of h = from 0.017 H to 0.023 H. When air was only partially admitted, the discharge was affected (*increased*) by less than one per cent. while *h* remained less than 0.15 H.

* These values are lower than those given in Art. 14 (*m*) and (*n*), and much lower than those in (*o*).

Dubuat's formula for submerged weirs. Let

H and h = the heads measured vertically from the crest a of the weir to the surface of still water* up-stream and down-stream from the weir, respectively.

$d = H - h$ = their difference = the difference in level between the up-stream and down-stream surfaces of still-water,*

c = coefficient of discharge = $\frac{\text{actual discharge}}{\text{theoretical discharge}}$.

Then

$$Q = c\,L\left(h + \frac{2}{3}\,d\right)\sqrt{2\,g\,d};\dagger \quad \ldots\ldots\ldots \quad (9) \text{ or:}$$

$$\text{Actual \textbf{discharge} in cub. ft. per sec.} = c \times \frac{\text{length of}}{\text{weir in ft.}} \times 8.025\,\sqrt{d \text{ in ft.}} \times \left(h \text{ in ft.} + \frac{2}{3}\,d \text{ in ft.}\right).$$

(n) **Messrs. Fteley and Stearns**‡ experimented at Boston in 1877 with **submerged weirs** under up-stream heads H from about 4 to 10 inches; and **Mr. Francis**§ at Lowell in 1883 under heads from about 1 foot to 2 feet 4 inches.

From these experiments we deduce the following

Table 16, of approximate values of the **coefficient c** in the formula for discharge over **submerged weirs.**

$$Q = c\,L\left(h + \frac{2}{3}\,d\right)\sqrt{2\,g\,d}.$$

Deduced from experiments by Fteley and Stearns and by J. B. Francis. In Mr. Francis' experiments, the value of c for a given value of $h \div H$ generally increased as H increased.

	Fteley and Stearns. (H = 0.325 to 0.815 feet.)	J. B. Francis. (H = 1 to 2.32 feet.)

* For velocity of approach, see Art. 14 (u) etc.

† In deducing this formula, the water that passes over the weir between c and b is assumed to flow as over a weir with its crest at b, and with free discharge into the air, as over the crest a in Fig. 20; and for this portion, by formula (2) in Art. 14 (l), the discharge would be:

$$Q_b = c\,L\,\frac{2}{3}\,d\,\sqrt{2\,g\,d};$$

while the water that passes through the lower portion between b and a is regarded as flowing through a submerged vertical *orifice* whose height is $b\,a = h$, under a head $= d$. For this lower portion, therefore, the discharge would be:

$$Q_a = c\,L\,h\,\sqrt{2\,g\,d}.$$

It is assumed that the coefficient of discharge c is the same for the upper section $c\,b$ as for the lower one $a\,b$. Hence, adding these two discharges together, we obtain, for the entire disharge:

$$Q = Q_b + Q_a = c\,L\left(h + \frac{2}{3}\,d\right)\sqrt{2\,g\,d}.$$

‡ Transactions, American Society of Civil Engineers, March, 1883, p. 101, etc.

§ Transactions, American Society of Civil Engineers, Sept., 1884, p. 295, etc.

(*t*) **Mr. Clemens Herschel,*** comparing these experiments with some earlier ones by Mr. Francis, gives the following:

Having ascertained the depths H and h of the crest below the still-water levels up-stream and down-stream respectively, divide h by H. Find the quotient, as nearly as may be, in the column headed $h \div H$ in Table 17. Take out the corresponding coefficient a, and multiply it by the up-stream head H.†

The product a H is the head which would cause the given weir to discharge the same quantity freely *into the air*, as in Fig. 20. Find the discharge into air over the given weir with the head a H; and this discharge will be approximately the same as that of the actual *submerged* weir under the up-stream head H and against the down-stream head h; or (H being the actual up-stream head on the *submerged* weir) the discharge is

$$Q = m\,L\,a\,H\,\sqrt{2\,g\,a\,H} = x\,L\,a\,H\,\sqrt{a\,H} \ldots\ldots \quad (10).$$

TABLE 17.

$h \div H$	a	$h \div H$	a	$h \div H$	a
.10	1.000 to 1.010	.45	0.894 to 0.930	.72	0.762 to 0.784

.25	0.960 to 0.984	.55	0.853 to 0.889	.76	0.732 to 0.752
.30	0.945 to 0.973	.60	0.829 to 0.863	.78	0.713 to 0.733
.35	0.928 to 0.960	.65	0.803 to 0.833	.80	0.693 to 0.713
.40	0.912 to 0.946	.70	0.775 to 0.799		

(*u*) **Velocity of approach.** See Fig. 24. It is generally impracticable to measure the head H′ to perfectly still water o' up-stream. The head is usually measured at a point o, from 2 or 3 to 6 or 8 feet or more up-stream from the weir, according to the size of the latter. At such points the velocity is generally appreciable, and the surface therefore a little lower than at o'. Hence a formula using the smaller head H so measured, instead of H′, and coefficients based upon H′, will give too small a discharge. Mr. Francis found that a current of 1 foot per second, or nearly 0.7 mile per hour, at the point o to which the head was measured, increased the discharge but about 2 per cent. when the head was 3 inches; and a current of 6 inches per second increased the discharge about 1 per cent. when the head was 8 inches.

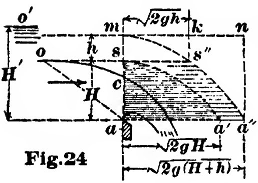

Fig.24

If, however, the velocity of approach is such as to require consideration, proceed as follows: For the approximate mean velocity of approach, we have:

$$v = \frac{\text{approximate discharge}}{\text{area of entire cross section of stream at } o} = \frac{3.33\ L\ H^{\frac{3}{2}}}{\text{area at } o};$$

and, for the head due to this velocity, $h = \dfrac{v^2}{2g}$

Then, for all practical purposes, we may say: $H' = H + h$; or

$$Q = m\,L\,(H + h)\,\sqrt{2\,g\,(H + h)} = x\,L\,(H + h)^{\frac{3}{2}} \ldots\ldots \quad (11)$$

Although, strictly speaking, the difference of level between o' and o is really (as shown in Fig. 24) somewhat *greater* than h, or than $v^2 \div 2\,g$, because some head is lost in friction between o' and o.

* Transactions, American Society of Civil Engineers, May, 1885, pp. 189, etc.

† Mr. Herschel's table, from which ours is condensed, gives a for every 0.01 foot of $h \div H$; but the values of a intermediate of those we have selected may be taken from our table almost exactly by simple proportion.

(*v*) **Messrs. Fteley and Stearns** make $H' = H + 1.5\,h$ for suppressed weirs, and $H' = H + 2.05\,h$ for weirs with complete end contractions, as averages; and Mr. Hamilton Smith, Jr.,* after comparing their experiments with others by Lesbros, Castel and Mr. Francis, gives $H' = H + 1\frac{1}{3}\,h$, and $H' = H + 1.4\,h$, for the two cases respectively.

(*w*) On the other hand, Mr. Francis' formula, as modified for velocity of approach,

$$Q = x\,L\dagger\left(\sqrt{(H+h)^3} - \sqrt{h^3}\right) = m\,L\dagger\sqrt{2g}\left(\sqrt{(H+h)^3} - \sqrt{h^3}\right)\ddagger \quad . \; . \; . \quad (12),$$

makes the effect of H' *less* than that of $H + h$.

(*x*) **Messrs. A. W. Hunking and Frank S. Hart,** Civil and Hydraulic Engineers, have substituted for the expression $(\sqrt{(H+h)^3} - \sqrt{h^3})$ in formula (12), the equivalent one $K\,\sqrt{H^3}$, in which K is a coefficient deduced from the former expression, and therefore depending upon the relation between H and *h*, or, ultimately, upon that between the cross-section *a s* Fig. 24 at the weir and the entire cross-section of the stream at *o*

Having found the area of cross section at *o*, divide it by $\left(L - n\,\frac{H}{10}\right)$, which is the length of the weir corrected for contraction. See Art. 14 (*m*). Call the quotient D.§ Divide the measured head H by D. Find this last quotient in the column $\frac{H}{D}$ of the table. Multiply the approximate discharge, $Q = 3.33 \left(L - n\,\frac{H}{10}\right) H^{\frac{3}{2}}$, by the corresponding coefficient K; or

$$\textbf{Actual Discharge}\ Q = 3.33\ K\left(L - n\,\frac{H}{10}\right) H^{\frac{3}{2}}. \quad . \; . \; . \; . \; . \quad (13)$$

Table 18. Coefficient K in formula (13).

* "Hydraulics," John Wiley & Sons, New York, 1886.

† If there are end contractions, L here becomes $\left(L - n\,\frac{H}{10}\right)$. See Art. 14 (*m*).

‡ This formula is deduced as follows: Let the area of the parabolic segment *a s a'*, Fig. 24, represent the theoretical discharge over a weir one foot long (as explained in foot-note § p. 549) under the measured head $H = a\,s$, as though there were no current at *o*. Let $m\,s = h = v^2 \div 2\,g$. The theoretical velocities of the particles passing the oblique plane *o a* under their actual heads, will now be represented by horizontal lines *s s''*, *a a''*, etc., etc., drawn from every point in *s a* to the *outer* curve *s'' a''*; the line *s s''* representing v = velocity of approach $= \sqrt{2\,g\,h}$, and *a a''* representing $\sqrt{2\,g\,(H+h)}$. Then, area *s s'' a'' a*

$$= \text{area } m\,a''\,a - \text{area } m\,s''\,s = \frac{2}{3}\ \text{area of rectangle } a\,n - \frac{2}{3}\ \text{area of rectangle } s\,k$$

$$= \frac{2}{3}\left(H + h\right)\sqrt{2\,g\,(H+h)} - \frac{2}{3}\,h\,\sqrt{2\,g\,h}, = \frac{2}{3}\sqrt{2\,g}\left(\sqrt{(H+h)^3} - \sqrt{h^3}\right);$$

and the actual discharge is

$$Q = c \times \text{length of weir} \times \text{area } s\,s''\,a''\,a = c\,L\,\frac{2}{3}\sqrt{2\,g}\left(\sqrt{(H+h)^3} - \sqrt{h^3}\right)$$

$$= m\,L\,\sqrt{2\,g}\left(\sqrt{(H+h)^3} - \sqrt{h^3}\right) = x\,L\left(\sqrt{(H+h)^3} - \sqrt{h^3}\right).$$

§ In a weir without end contraction, $D = H + p$.

K is very approximately $= 1 + \frac{1}{4}\left(\frac{H}{D}\right)^2$ Hence

$$Q = 3.33\left[1 + \frac{1}{4}\left(\frac{H}{D}\right)^2\right]\left(L - n\,\frac{H}{10}\right)H^{\frac{3}{2}}$$

$$= \left[3.33 + 0.83\left(\frac{H}{D}\right)^2\right]\left(L - n\,\frac{H}{10}\right)H^{\frac{3}{2}}. \quad . \quad . \quad . \quad (14)$$

See Journal of the Franklin Institute, Philadelphia, August, 1884, from which we condense the above table

(*y*) **M. Bazin**, see Art. 14 (*o*), provides for the velocity of approach by modifying the coefficient m instead of the head H, making $\dot{m} = 0.425 + 0.21\left(\frac{H}{D}\right)^2$; while by Messrs Hunking and Hart's method (based upon Mr. Francis' experiments) m becomes $= 0.415 + 0.10\left(\frac{H}{D}\right)^2$.

Art. 15. Inclined weirs. If the up-stream face of the weir, instead of being vertical, as in Fig. 25, is inclined up-stream, as in Fig. 25 *a*, or down-stream, as in Fig. 25 *b*, the character and amount of the discharge are modified With an up-stream inclination (Fig 25 *a*) the lower side of the sheet of water passing over the weir leaps higher, and tends more and more up-stream as the

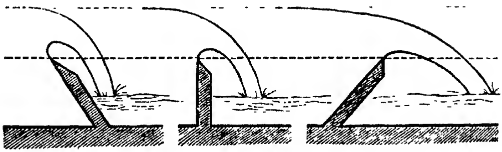

Fig. 25 *a*. **Inclined up-stream.** Fig. 25. **Vertical.** Fig 25 *b*. **Inclined down-stream.**

inclination is increased With a down-stream inclination (Fig 25 *b*), on the contrary, as the inclination increases the upward leap of the sheet decreases, its profile becomes more and more flattened, and the curve of the upper surface, due to the fall, extends farther up-stream from the crest of the weir.

An up-stream inclination (Fig 25 *a*) decreases, and a down-stream one (Fig. 25 *b*) increases, the discharge, as is indicated by the following coefficients obtained by M. H. Bazin:*

For the discharge over an inclined weir, having ascertained the discharge over a vertical weir of the same height and head and under similar conditions in other respects, multiply the discharge over the vertical weir by the following approximate coefficients·

	Inclination.		Angle		Coefficient.
	Horizontal.	Vertical.	with hor.	with vert.	
Weirs inclined up-stream, Fig. 25 *a*....	1	1	45°	45°	0.93

* "Expériences Nouvelles sur l'Écoulement en Déversoir," 2e Article; "Annales des Ponts et Chaussées," January, 1890, translated in *Proceedings, Engineers' Club of Philadelphia*, vol. ix., 1892.

The discharge will be increased also if the inner corner or edge of the crest be rounded off, instead of being left sharp; or if the sides of the reservoir converge more or less as they approach the weir, so as to form wings for guiding the water more directly to it; or if *a b*, Fig 20, be less than twice *a m*. Indeed, so many modifying circumstances exist to embarrass experiments on this and similar subjects that some of those which have been made with great care are rendered inapplicable as other than tolerable approximations, in consequence of the neglect to take into consideration some local peculiarity which was not at the time regarded as exerting an appreciable effect. Unless, therefore, circumstances admit of our combining all the conditions mentioned in Art. 14 (*d*), (*f*) and (*m*), pp. **547**, **548** and **550**, thereby securing *very* approximate results, we must either resort to an actual measurement of the discharge in a vessel of known capacity; or else be content with rules which may lead to errors of 5, 10, or more per cent in proportion as we deviate from these conditions. Frequently even 10 per cent. of error may be of little real importance.

REMARK 1. When the water, after passing over a weir, Fig. 26, instead of fall-

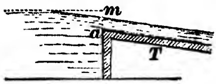

Fig. 26.

ing freely into the air, is carried away by a slightly inclined apron or trough, T, the floor of which coincides with the crest *a*, of the weir, then the discharge is not appreciably diminished thereby when the head *a m*, is 15 inches or more. But if the head *a m* is but 1 foot, then the calculated discharge must be reduced about one-tenth; if 6 inches, two-tenths; if 2½ inches, three-tenths; and if 1 inch, five-tenths, or one-half, as approximations.

REMARK 2. Professor Thomson, of Dublin, proposed the use of triangular notches, or weirs, for measuring the discharge, inasmuch as then the periphery always bears the same ratio to the area of the stream flowing over it; which is not the case with any other form. Experimenting with a right-angled triangular

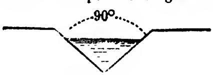

Fig. 26 A.

notch in thin sheet-iron, Fig. 26 A, with heads of from 2 to 7 inches, measured vertically from the bottom of the notch to *the level surface of the quiet water*, he found *discharge* in cubic feet per second = .0051 × $\sqrt{\text{fifth power of head in inches}}$ = 2.54 × $\sqrt{\text{fifth power of head in feet}}$* Or, in general, if m = coefficient of contraction (Art. 9, p 541) T = tangent of ½ the angle of the notch = ½ width of water-surface ÷ the depth in the notch, g = the acceleration of gravity = say 32 2 feet per second, and h = the head, measured as above; then

$$\text{Discharge} = \frac{8m}{15}\, T \sqrt{2 g h^5}\,^* = 4.28\, m\, T \sqrt{h^5}.^*$$

Remark 3. In constructing the irrigating canal, Canale Villoresi, near Milan, in 1881–4, the Italian engineer, Cesare Cippoletti,† adopted **a trapezoidal notch**, with its bottom edge horizontal and its ends sloping at $\frac{4 \text{ vertical}}{1 \text{ horizontal}}$, in order to avoid the necessity of either suppressing or allowing for end contractions. (See Art. 14 *c*, p **547**, and *m*, p **550**.) The contraction was found to affect only the triangular spaces over the sloping ends of the weir, and the effective length of the weir thus remained constant (and equal to the length of the bottom edge) for all heads. In using these weirs the contraction is complete along the bottom as well as at the ends.

* For such roots see p. 68.

† See his work, *Canale Villoresi; Modulo per la Dispensa della Acqua, etc.*, **Milan**, 1886; published by Societa Italiana per Condotte d'Acqua. **Results summarized by** L. G. Carpenter, in Bulletin No. 13, Agricultural Experiment Station, Fort Collins, Colorado, October, 1890.

ON THE FLOW OF WATER IN OPEN CHANNELS.

Art. 16. The mean velocity of flow is an imaginary uniform one, which, if given to the water at every point in the cross section, would give *the same discharge* that the actual ununiform one does. Or

$$\textbf{mean velocity} = \frac{\text{volume of discharge}}{\text{area of cross section}}$$

In channels of uniform cross section, **the maximum velocity** is found about midway between the two banks, and generally at some dist below the surface. This dist varies in diff streams; but, as an average, it seems to be about one third of the total depth. Where the total depth is great in proportion to the width, (say ½ the width or more), the max vel has been found as deep as midway between surf and bottom; while in small shallow streams it appears to approach the surf to within from .1 to .2 of the total depth. Many experiments upon shallow streams have indeed indicated that the max vel was *at* the surf.

The ratio between the velocities in different parts of the cross section varies greatly in diff streams; so that but little dependence can be placed upon rules for obtaining one from the other. With the same surf vel, wide and deep streams have greater mean and bottom vels than small shallow ones. In order **to approximate roughly to the mean vel** when the greatest surf vel is given, it is frequently assumed that the former is = ⅘ (or .8) of the latter. But Mr. Francis found, in his experiments at Lowell, that *surface* floats of wax, 2 ins diam, floating down the center of a rectangular flume 10 ft wide, and 8 ft deep, actually moved about 6 per cent *slower* than a tin tube 2 ins diam, reaching from a few ins above the surf, down to within 1½ ins of the bottom of the flume; and loaded at bottom with lead, to insure its maintaining a nearly vert position. While the wax *surf* float moved at the rate of 3.73 ft per sec, the rate of the tube (which was evidently very nearly the same as that of the center *vert* thread of water) was 3.98 ft per sec. Also, that in the same flume, with vels of the center tube varying from 1.55 to 4 ft per sec, the vel of the tube was *less* than that of the mean vel of the entire cross section of water in the flume, about as .96 to 1, for the lesser vel; and .93 to 1 for the greater vel. While, in another rectangular flume 20 ft wide and 8 ft deep, with vels varying from 1.16 to 1.84 ft per sec, that of the tubes was *greater* than that of the entire mass of water, about as 1.04 to 1. In a flume 29 ft wide, by 8.1 ft deep, with vels of about 3 ft per sec, it was as 1 to .9; and in a flume 36½ ft wide, by 8.4 ft deep, with vels of about 3½ ft per sec, as 1 to .97.

Charles Ellet, Jr, C E, found in the Mississippi "at diff points *on the river, in depths varying from 54 to 100 ft; and in currents varying from* 3 to 7 miles an hour that the speed of a float supporting a line 50 ft long, is almost always grea er than that of the surf float alone." The same results were obtained with lines 25 and 75 ft long; the excess of the speed of the line floats being about 2 per cent over that of the simple floats: and Mr. Ellet concludes, therefore, that the mean vel of the entire cross section of the Mississippi, instead *of being less, is absolutely greater by about 2 per cent, than the MEAN surf vel. He, however, employed .8 of the greatest surf vel as representing approximately,* in his opinion, the mean vel of the *entire* cross section of water. In *shallow* streams, he always found the surf float to travel more rapidly than a line float.

European trials of the *mean* vel of *separate single verticals*, in tolerably deep rivers, have resulted in from .85 to .96 of the surf vel at each vertical. The mean *of all may be taken at .9.*

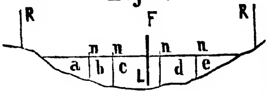
Bottom velocity. In streams of nearly uniform slope and cross section, there is a great reduction of vel near the bottom. As a very rough approximation, the deepest measurable vel, in streams of uniform slope etc, appears to be from ½ to ⅔ of the mean vel.

Art. 17. To measure the surface velocity, select a place where the stream is for some dist (the longer the better) of tolerably uniform cross section; and free from counter-currents, slackwater, eddies, rapids, etc. Observe, by a seconds-watch, or pendulum, how long a time a float (such as a small block of wood), placed in the *swiftest* part of the current, occupies in passing through some previously measured dist. From 50 feet for slow streams, to 150 ft for rapid ones, will answer very well. This dist in ft, or ins, div by the entire number of seconds reqd by the float to traverse it, will give the greatest surf vel in ft or ins per sec.

The surf vel should be measd in perfectly calm weather, so that the float may not be disturbed by wind; and, for the same reason, the float should not project much above the water. The measurement should be

repeated several times to insure accuracy. In very small streams, the banks and bed may be trimmed for a short dist, so as to present a uniform channel-way. The float should be placed in the water a little dist above the point for commencing the observation; so that it may acquire the full vel of the water, before reaching that point.

Fig 27



Art. 18. To gauge a stream by means of its velocity. Select a place where the cross-section remains, for a short distance, tolerably uniform, and free from counter-currents, eddies, still water, or other irregularities Prepare a careful cross-section, as Fig 27 By means of poles, or buoys, *n. n.* divide the stream into sections, *a. b. c.* &c Plant two range-poles, R R, at the upper end, and two others at the lower end, of the distance through which the floats are to pass: for observing, by a seconds watch or a pendulum, the time which they occupy in the passage Then measure the *mean* velocity of each section *a. b. c.* &c, separately, and directly, by means of long floats, as F L, reaching to near the bottom: and projecting a little above the surface. The floats may be tin tubes, or wooden rods; weighted in either case, at the lower end, until they will float nearly vertical. They must be of different lengths, to suit the depths of the different sections. For this purpose the float may be made in pieces, with screw-joints. The area of each separate section of the stream in square feet, being multiplied by the observed mean velocity of its water in feet per second, will give the discharge of that section in cubic feet per second And the discharges of all the separate sections, thus obtained, when added together, will give the total discharge of the stream. And this total discharge, divided by the entire area of cross-section of the stream in square feet, gives the mean velocity of *all* the water of the stream, in feet per second.

Rem. If the channel is in common earth, especially if sandy, the loss by soakage into the soil, and by evaporation, will frequently abstract so much water that the disch will gradually become less and less, the farther down stream it is measured. Long canal feeders thus generally deliver into the canal but a small proportion of the water that enters their upper ends.

The double float is used for ascertaining vels at diff depths. It consists of a float resting upon the surface of the water, and of a heavier body, or "lower float", *which is suspended from the upper float by means of a cord.* The depth of the lower float of course depends upon the length of the suspending cord (which may be increased or diminished at pleasure until the lower float is believed to be at that depth for which the vel is wanted), and upon its straightness, which is more or less affected by the current. Owing to this latter circumstance, it is difficult to know whether the lower float is really at the proper depth. *Moreover it is uncertain to what extent the two floats and the string* interfere with one another's motions. In deep water the string may oppose a greater area to the current than the lower float itself does. It thus becomes doubtful to what extent the vel of the upper float can be relied upon as indicating that of the water at the depth of the lower one.

Art. 19. Castelli's quadrant, or hydrometric pendulum, consisted of a metallic ball suspended by a thread from the center of a graduated arc. The instrument was placed in the current, with the arc parallel to the direction of flow; and the vel was then calculated from the angle formed between the thread and a vert line.

Gauthey's pressure plate was a sheet of metal suspended by one of its ends, about which it was left free to swing. The plate was immersed in the stream, with its face at right angles to the current. The vel was estimated by means of the weight required to make the plate hang vert in opposition to the force of the current.

Pitot's tube was originally a simple glass tube, Fig 27 A, open at both ends and bent in the shape of the letter L. One leg of the L was held horizontal under water, with its open end facing the current; and the velocity v at the point o where it was placed was measured by the vertical height h $\left(\text{theoretically} = \frac{v^2}{2g}\right)$ to which the water rose in the other leg above the surface of the stream.

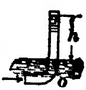


Fig. 27A

As developed by M. Darcy and by Prof. S. W. Robinson,* and rudely indicated in Fig. 27 B, Pitot's tube consists essentially of *two* horizontal glass or metal tubes *a* and *b*, of very small bore, placed side by side in the current and pointed up-stream. Tube *a* receives the current in its open up-stream end, while *b* is closed at its up-stream end, and has small *lateral* openings only. The other end of each tube communicates, by means of small metal or rubber piping, with one leg of an inverted U shaped glass gauge fixed in a boat or on shore. For convenience, the two flexible pipes may be joined together into one double pipe. By sucking through a stop-cock T at the top, water is drawn up to any convenient height in the two legs of the gauge. When measuring the flow in pipes under pressure, such suction is unnecessary, and a U-shaped manometer is commonly used, the U being filld with a liquid heavier than water. When there is no current, the two columns of course stand at the same level; but, when a current is flowing, they stand at diff levels, as in Fig 27B, and the velocity is given by the equation, $v = c\sqrt{2\,g\,h}$

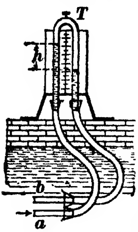

Fig. 27B

where h = the diff of level of the two column-tops, v = the vel of the water at the point where it impinges upon tube a, g = acceleration of gravity = 32 2 ft (9.81 meters) per sec per sec, and c = an experimental coefficient, found preferably by rating the apparatus in a current of known vel. When the hor end of tube b is drawn to a long, smooth, fine point, facing the current, and its (tangential) orifices are placed at some dist down-stream from said point and are made small, and their edges carefully smoothd, to avoid disturbance of flow, the coeff c approximates very closely to unity, so that, for practical purposes, $v = \sqrt{2\,g\,h}$. The instrument is remarkably simple and accurate, and can be used in very narrow and shallow streams of water or of gas. It measures velocities as low as 4 inches per second.

In practice, a and b are fixed together in one piece, and placed, when in use, in a metal frame which slides vertically, either upon a wire passing through it and provided with a plummet which rests upon the bottom and keeps the wire stretched, or (in streams shallower than about 20 feet) upon a vertical wooden rod, the lower end of which holds in the bed of the stream. In the former case, the frame is provided with a long vane for keeping the instrument headed upstream. In either case, means are provided for showing the depth to which the instrument is submerged

By making the gauge scale adjustable vertically, and placing it (at each change of depth of instrument) with its zero opposite the top of the lower column, we obviate the necessity of observing the height of both columns at each reading; for the reading of the upper column alone then gives the head h at once.

Art. 20. The wheel meter consists of a wheel which is turned by the current, and which communicates its motion, by means of its axle and gearing, to indices which record the number of revolutions. The instrument may be clamped to any part of a long pole reaching to the bottom of a stream, and thus may be used at any depth The observer, by means of a wire, rod or string reaching down to the instrument, throws the registering apparatus first into, and then out of, gear with the wheel (applying a brake to the former at the instant it is thrown out of gear), and carefully noting the times when he does so. The instrument is then raised, the number of revolutions in the measured time is read off from the indices, and from it the velocity is calculated But the meter is often made **self-registering**; the wheel, at each revolution, automatically breaking and re-establishing a galvanic current generated by a battery. The wire carrying this current is thus made to operate Morse telegraphic registering apparatus placed in a boat or on shore

A number of meters, so arranged, can be attached at different points on the same pole at the same time, and thus **simultaneous observations of velocities at different depths** may be made and registered.
